INDEX TO VOLUME CXLI.

Abdominal Surgery. Treatment of patients after abdominal section, Bonifield, C. L., 117; acute abdominal symptoms demanding immediate surgical intervention, Richardson, M. H., 381, 405, 433; reopening the abdomen for post-operative septic peritonitis, Frederick, C. C., 325; the sphere of drainage in surgery of the appendix, MacLaren, W. S., 327; appendicitis: its treatment from a medical and surgical standpoint, Scully, T. B., 527.

Abortion. Necessary abortion, Bowers, W. C., 117.

Accidents and lawsuits, 171.

Acker, G. N. Porencephalus, case and specimen, 368.

Actinomycosis. A case of actinomycosis, operation, recovery, Mixter, S. J., 10; the pathology of actinomycosis, Wright, J. H., 10; cases of actinomycosis, Elliot, J. W., 11.

Adams, C. Insanity in its relation to crime, 113.

Adams, S. S. Sarcoma of the cerebellum in a child aged four years, 369.

Addresses. Annual discourses and addresses, an explanation, 47.

Advertising, or being advertised, Phelps, A. M., 563.

Air. The tonic properties of sea-air, 226.

Albuminuria, its prognostic value in chronic nephritis, Tuttle, C. A., 323.

Alcohol. The treatment of inebriety, 72.

Allbutt, C. Conception of disease, 506.

Allen, D. A. Exstrophy of the bladder, 45.

Allen, D. P., and Briggs, C. E. Division of a ureter with successful end-to-end suture of the same in a case of horse-shoe kidney, 344.

Ambler, C. P. Some statistics upon serotherapy in tuberculosis, with report of 100 cases so treated in 1898, combined with a favorable climate and with strict supervision of the patient, 21.

Ambulance. The new army ambulance, 399.

Anatomy. The sexual differences of the fetal pelvis, 97; transposition of the viscera and of the great vessels, with photograph, Griffith, J. P. C., 394; observations on certain abnormal conditions in livers of infants and children, Freeman, R. G., 394.

Anders, H. S. The relation of local meteorological conditions to the influenza epidemic in Philadelphia of 1898-1899, 246.

Anderson, B. F. Intermediate altitude for the consumptive, 219.

Anesthesia. The administration of nitrous oxide with air or with oxygen, Brunett, T. L., 527.

Aneurism. Treatment of popliteal aneurism by excision, Oliver, J. C., 46.

Animals. Further prevention of cruelty to animals in the District of Columbia: Senate Bill No. 34, Keen, W. W., 643.

Appendicitis as a cause of inflammation of the right ovary and tube, Oehsner, A. J., 42; complications and sequels of appendiceal abscess, Deaver, J. B., 43; diagnosis and treatment of appendicitis, with report of 102 cases, Means, 43; inquiries in the etiology and treatment of appendicitis, Harsha, W. H., 43; hernia following operations for appendicitis, Harrington, F. B., 165; some points regarding appendicitis, Campbell, B. P., 303; the sphere of drainage in surgery of the appendix, MacLaren, W. S., 327; appendicitis, its treatment from a medical and surgical standpoint, Scully, T. B., 527; simulated appendicitis, Mumford, J. G., 602.

Army. The rank and pay of the surgeon-general, 27; the female nurse corps of the army, 74; improvements in army medical service suggested by experience in the late war, Devine, W. H., 157; an army sanitarium for tuberculosis, 284; progress in military sanitation, 326; a new course of instruction for the army hospital corps, 375; the new army ambulance, 399; an object lesson in military sanitation, Greenleaf, C. R., 485; tentage for tropical service, Munson, E. L., 487; chances of death in war, 534; the female nurse in the army, 558; legislation for the army medical service needed, 563; army medical bills, 568; the army ration, Smart, C., 587; contract surgeons in the United States Army, Munson, E. L., 588; free medical aid to soldiers' families, 641.

Arnold, H. D. The transmission of systolic mitral murmurs, with special reference to the nature of the so-called anemic murmurs, 16.

Ashmead, A. S. Excision of fat from the dietary is not a cause of beri-beri, 535.

Athletes. English *vs.* American athletes, 95.

Athletics and patriotism, 806.

Austin, A. E. The nutritive value of albumose peptone, 545.

Autopsy. Some results of enthusiasm, 630.

Ayres, D. Some practical experience in asepsis and antisepsis in obstetrics, 499.

Babcock, R. H. High altitude and heart disease, with report of cases, 198, 217.

Bacteriology. A new pathogenic microbe of sewage, Klein, E., 98; the rôle of the staphylococcus in skin diseases, White, C. J., 235.

Bailey, W. Vaccination, 578.

Baker, F. H. A report of medico-legal autopsies, 465, 472.

Bartlett, W. Does the present method of securing expert testimony subserve the ends of justice? 500.

Baruch, S. Hydriatic measures in the management of the febrile disorders of infancy and childhood, with a practical demonstration of various hydriatic procedures, 475.

Bath. A new bath facilitating hydrotherapy in private practice, Haven, A. C., 19.

Beach, H. H. A. Anatomical specimens, 630.

Beach, W. M. Some complications resulting from rectal operations, 68.

Beer drinking, 562.

Bennett, T. L. The administration of nitrous oxide, with air or with oxygen, 527.

Bequest. A notable bequest, 24.

Beri-beri. The etiology of beri-beri, 274; exclusion of fat from the dietary is not a cause for beri-beri, Ashmead, A. S., 535.

Bevan, A. D. Operation for undescended testicle and congenital hernia, 44.

Bibliography. Abbott, A. C., the hygiene of transmissible diseases; their causation, modes of dissemination and methods or prevention, 580; Allen, C. W., hand-book of medical progress, 609; Anders, J. M., a text-book of the practice of medicine, 477; Attfield, J., chemistry, general, medical and pharmaceutical, including the chemistry of the U. S. Pharmacopœia, 89; Baruch, S., the principles and practice of hydrotherapy, 477; Bastian, H. C., a treatise on aphasia and other speech defects, 322; Bannatyne, G. A., rheumatoid arthritis, its pathology, morbid anatomy and treatment, 397; Bell, J., notes on surgery of nurses, 608; Bennet, W. H., on varix, its causes and treatment, with especial reference to thrombosis, 609; Bianchi, A., the phonendoscope and its practical application, 580; Birch, De B., a class-book of (elementary) practical physiology, including histology, chemical and experimental physiology, 256; Blake, E., on the study of the hand for indications of local and general disease, 299; Boston City Hospital report, 299; Bramwell, B., anemia and some of the diseases of the blood forming organs and ductless glands, 529; Brissaud, E., leçons sur les maladies nerveuses, 397; Brubaker, A. P., a compend of human physiology, 398; Bruce, J. M., materia medica and therapeutics, 371; Burdett, H., hospitals and charities, 1899, 301; Caton, R., two lectures on the temples and rituals of Asklepios at Epidaurus and Athens, 608; Clouston, F. S., clinical lectures on mental diseases, 70; Coakley, C. G., a manual of diseases of the nose and throat, 608; Cobianchi, V., the newer remedies, 70; Crile, G. W., an experimental research into surgical shock, 608; Crook, J. K., the mineral waters of the United States and their therapeutic uses, 608; Culbertson, J. C., Luke, the beloved physician, 70; Cushny, A. R., a text-book of pharmacology and therapeutics, or the action of drugs in health and disease, 371; Dastre, A., and Florence, N., recherches sur les matières colorantes du foie et de la bile et sur le fer hepatique, 665; Donders, F. C., an essay on the nature and the consequences of anomalies of refraction, 373; Dorland, W. A. N., American medical pocket dictionary, 373; Dowse, T. S., the treatment of disease by physical methods, 69; Foster, M., Claude Bernard, 609; Fuchs, E., text-book of ophthalmology, 397; Fuller-ton, A. M., hand-book of obstetric nursing for nurses, students and mothers, 636; Gerrish, F. H., text-book of anatomy by American authors, 23; Goff, J. E., hand-book of materia medica for trained nurses, 143; Gordinier, H. C., the gross and minute anatomy of the central nervous system, 652; Gould, G. M., and Pyle, W. L., a compend of diseases of the eye and refraction, including treatment and surgery, 373; Haab, O., Saunders' medical hand-atlases, 373; Hampton, L. A., nursing; its principles and practice for hospitals and private use, 529; Hausell, H. F., a practical hand-book on the muscular anomalies of the eye, 373; Hare, H. A., the medical complications, accidents and sequelæ of typhoid or enteric fever, 501; physical diagnosis, 610; Heffcrich, H., on fractures and dislocations, 608; Heitzmann, L., urinary analysis and diagnosis, 118; Herrick, C. B., railway surgery, 581; Hinsdale, G., acromegaly, 477; Hirst, B. C., a text-book of obstetrics, 636; Hirt, L., the diseases of the nervous system, 453; Holtopeter, W. G., hay-fever and its successful treatments, 199; Jakesh, R. v., clinical diagnosis, 397; Kingscote, E., asthma, recent developments in its treatment, 580; Lake, R., international directory of laryngologists and otologists, containing names and addresses of practitioners engaged in the study and practice of laryngology and otology, 477; Lane, L. C., the surgery of the head and neck, 69; Lenné, A., Wesen, Ursache und Behandlung der Zuckerkrankheit (diabetes mellitus), 170; Luff, A. P., gout, its pathology and treatment, 606; Maisch, J. M., Maisch's materia medica, 23; Measham, L. J., lessons in hypnotism and the use of suggestion based upon the neuron motility hypothesis, 143; Morison, A., on the relation of the nervous system to disease and disorder in the viscera, 221; Mracek, F., Saunders' medical hand-atlases, 557; Musser, J. H., a practical treatise on medical diagnosis for students and physicians, 636; navy, annual report of the surgeon-general of the, 503; Newsholme, A., the elements of vital statistics, 22; Nothnagel, H., specielle Pathologie und Therapie,

501; Novy, F. G., laboratory work in bacteriology, 93; Ohlemann, F. W. M., ocular therapeutics for physicians and students, 372; Ostrom, K. W., massage and the Swedish movements, 477; Platt, J. E., a contribution to the surgery of fractures and dislocations of the upper extremity, 637; Praun, E., die Verletzungen des Auges, 372; Rodes, D. B. St. J., defective eyesight and the principles of its relief by glasses, 636; Savill, T. D., clinical lectures on neurasthenia, 221; Sayre, L. E., a manual of organic materia medica and pharmacognosy, 637; Schleif, W., materia medica, therapeutics, medical pharmacy, prescription writing and medical Latin, 425; Scott, J. F., the sexual instinct, its uses and dangers as affecting heredity and morals, 666; Schweinitz, G. E. De, diseases of the eye, 501; Skene, A. J. C., electro-hemostasis in operative surgery, 372; Smith, D. T., the philosophy of memory and other essays, 199; Stedman, T. L., twentieth century practice, 452; Stelwagon, H. W., Saunders' question-compends, No. 11, 858; Stewart, G. N., a manual of physiology with practical exercises, 637; Stricker, L., the crystalline lens system, 70; Talbot, E. S., degeneracy, its causes, signs and results, 221; Tebb, W. S., a century of vaccination and what it teaches, 93; Thompson, St. C., the cerebro-spinal fluid; its spontaneous escape from the nose, 373; Thorington, J., retinoscopy in the determination of refraction at one metre distance, with the plane mirror, 373; Vecki, V., sexual impotence, 667; Walker, L., an introduction to dermatology, 586; Williams, H. N., a manual of bacteriology, 93; Wolff, L., essentials of medical chemistry, 666; Wood, G. B., and Bache, F., the dispensatory of the United States of America, 636.

Bicycle. The cycle as an instrument of diagnosis, 438.

Biggs, H. H. The advance in our knowledge of typhoid fever, 526.

Bile. Contributions to the surgery of the bile passages, especially of the common bile-duct, Halsted, W. S., 645, 661.

Biography. Brechin, W. P., 616; Bleecker, E., 508; Bunsen, R. W. E., 189; Chamberlain, C. N., 99; Clendenin, P., 51; Cammer, W. H., 223; Cannedy, H. C., 3-0; Deane, A. C., 484; Ellis, C., 51; Fabricius, J. W., 73; Feeley, C. J., 252; Fenn, J. H., 373; Geary, J. S., 99; Gresham, J. E., 52; Hochausen, C. H., 508; Hoffman, W. M., 508; Hutchins, J., 432; Holmes, O. W., 534; Jiminez, P. Y., 404; Johnson, F. L., 644; Jenks, T. L., 458, 460; Ketch, S., 644, 670; Linson, J. J., 252; Lockwood, W. A., 616; McLaughlin, J. A., 432; McLeod, S. H. W., 243; Meller, J., 357; McCreery, J. S., 535; Miller, E., 616; Neilson, W. H., 52; Niedecker, J. W., 99; Phillips, J. K., 484; Robinson, T. C., 304; Scheer, P., 460; Smith, J. H., 3-0; Sturgis, R., Jr., 76, 99; Schureman, J. C., 174; Taylor, C. F., 140; Thomas, F. A., 252; Tucker, J. J., 304; Wallach, J. G., 564; Woodbridge, L. D., 484.

Bishop, L. F. The diagnosis and treatment of thoracic effusions, 21.

Blake, C. J. A hospital clearing house, 186.

Blake, H. G. A case of ptomaine poisoning, 463, 472.

Blake, J. B. Administration of ether at the Boston City Hospital, 312 310.

Bleecker, A. N. Cyclical, or periodical, vomiting, 314; warning, 459.

Blood. On the value of blood examinations in the diagnosis of camp fevers, a report of the blood examinations in typhoid fever and in the malarial fevers, Curry, J. J., 513.

Boland, E. S. Unlooked-for dystocia in certain multiparæ, 654, 664.

Bonifield, C. L. Treatment of patients after abdominal section, 117.

Bonney, S. G. Suggestions concerning early diagnosis in pulmonary tuberculosis, 197.

Boody, G. Two epidemics of typhoid fever in the Iowa Hospital for the Insane, 18.

Boston Health Department, 427.

Bowditch, V. Y. The subsequent histories of "arrested cases" of phthisis treated at the Sharon Sanitarium, 193.

Bowen, J. T. Report on progress in dermatology, 317, 345; two epidemics of alopecia areata in an asylum for girls, 350.

Bowers, W. C. Necessary abortion, 117.

Brackett, H. M. Report of the committee on a national home for lepers in the United States, 579.

Brackett, E. G. Volunteer aid work in foreign territory, 188.

Bradford, E. H., and Brackett, E. G. The forcible correction of lateral curvature, 140; correction in lateral curvature, 277.

Bradford, E. H., and Stone, J. S. School seats, 338.

Branham, J. J. Temporary ligation of the common carotid artery during removal of large tumors about the face, with report of a case, 64.

Brigham, C. B. Extirpation of the stomach, 431.

Brooks, L. J. Subnormal temperature, 528.

Brooks, M. A. Operations in the treatment of palmar abscess, 133.

Brownrigg, A. E. Acute universal eczema, with special reference to its etiology, 572.

Brush, E. C. The use of acetanilid in typhoid fever, 19.

Bryce, P. A. Report of the committee on the cause and prevention of infectious diseases, 556.

Building Laws. Improved building laws for New York, 374.

Bulkley, L. D. Imperfect or deficient urinary secretion as observed in connection with certain diseases of the skin, 349.

Bull, C. S. Operative treatment of high myopia by removal of the crystalline lens, 498.

Burr, G. E. The thyroid gland and the menopause, 624.

Burrell, H. L. and Cushing, H. W. Recent progress in surgery, 548, 575, 603.

Burrage, W. L. A case of adenocarcinoma of the body of the uterus simulating submucous fibromyoma, 438; a case of ovarian cyst with twisted and strangulated pedicle, 470.

Cabot, A. T. Notes on the closure, by buried sutures, of rents which implicate the anal sphincter, 658.

Cabot, R. C. A case of chronic cyanosis without discoverable cause, ending in cerebral hemorrhage, 574.

Cabot, R. C., and White, F. W. Preliminary note on the prognosis of nephritis, 134.

Campbell, H. F. Some points regarding appendicitis, 306.

Cancer Further report on the catapheric treatment of cancer, Massey, G. B., 18; the prophylaxis of uterine cancer, Grant, W. W., 115; the prevention and treatment of cancer of the uterus, Smith, A. L., 116; an inquiry as to the increase and infectiousness of cancer, 641.

Carcinoma. The growth and extension of carcinoma, Councilman, W. T., 256; carcinoma under the age of thirty, Cumston, C. G., 435.

Casselberry, W. E. Address before the American Laryngological Association, 268.

Catalogue. An international catalogue of scientific literature, 398.

Centralblatt. A proposed card centralblatt, 300.

Cerebro-spinal meningitis, Miller, T. N., 14.

Channing, W. An interesting testimonial, 205.

Chapman, H. C. A treatise on human physiology, for the use of students and practitioners of medicine, 581.

Charity. Abuse of hospital charity by people able to pay, Gordon, S. C., 138; public money for private charities in New York, 373.

Chemistry. The proteids of the urine, Hills, W. B., 139, 157; the phenylhydrazin test for sugar in the urine, Coriat, I. H., 518.

Children. Report on diseases of children, Rotch, T. M. and Wentworth, A. H., 12, 628; x-ray examinations in children, Williams, F. H., 41; the treatment of the acute diarrhœas of infancy, Morse, J. L., 101; excessive crying of infants, Crocker, S. E., 227; American Pediatric Society, 367; the increase of weight of infants fed artificially, Koplik, H., 368; porencephalus; case and specimen, Acker, G. N., 368; sarcoma of the cerebellum in a child four years old, Adams, S. S., 369; enlarged bronchial nodes, West, J. P., 369; transposition of the viscera and of the great vessels, with photograph, Griffith, J. P. C., 394; observations on certain abnormal conditions in the eyes of infants and children, Freeman, S. E., 394; meningitis due to the typhoid bacillus, Wentworth, A. H., 394; acute articular rheumatism in infants under one year, with report of a case, Miller, D. J. M., 395; urticaria of the mucous membranes, Packard, F. A., 396; the renal complications of the acute enteric diseases of infancy, Morse, J. L., 396; scurvy in an infant of six weeks, Crandall, F. N., 396; congenital cystic kidneys, with a report of a case, Graham, E. E., 396; a case of multiple osteomyelitis in an infant, Rotch, T. M., 396; cause and prevention of infant mortality, Wende, E., 577.

Cholangiectomy, Ricketts, M., 577.

Cholecystotomy, 87.

Cholecystitis, Stockton, C. G., 20.

Christmas at the hospitals, 666.

Chronic Disease. The hospital for chronic disease, Taylor, E. W., 542, 553.

Circulatory System. A comparison of the various methods of estimating hemoglobin, Linnell, B. M., 14; treatment of the heart in chronic intestinal nephritis, Elliott, A. R., 15; a cause and differential diagnosis of accidental heart murmurs, Webster, G. W., 15; the transmission of systolic mitral murmurs with special reference to the nature of the so-called anemic murmurs, Arnold, H. D., 16; the examination of stained specimens of blood in the lymphatics by clinical work, Hewes, H. F., 38, 59; treatment of popliteal aneurism by excision, Oliver, J. C., 46; temporary ligation of the common carotid artery during removal of large tumors about the face, with report of a case, Branham, J. J., 64; the value of the pulse in diagnosis and prognosis, Jackson, H., 151; unusual diastolic murmur with autopsy, Lee, E., and Peacock, R. M., 162; high altitude and heart disease, with report of cases, Babcock, R. H., 196, 217; recent inquiries concerning blood changes induced by altitude, Solly, S. E., 218; report on progress in thoracic diseases, Sears, G. G., and Bartol, J. W., 240, 268; functional cardiac murmurs, Jacobi, A., 243; the value of embolism on the course of valvular heart disease, Gibson, W. M., 285; the cardiac asthenia of pneumonia, Elsner, H. L., 245; the effects of violent and prolonged muscular exercise upon the heart Williams, H., 245; cardio-esophageal gush and click simulating a heart murmur, Curtin, R. G., 246; septic phlebitis with thrombus as a complication of peritonsillar abscess, Ward, M. R., 297; functional murmurs of the heart, Jackson, H., 408, 432; a case of chronic cyanosis without discoverable cause, ending in cerebral hemorrhage, Cabot, R. C., 574; spontaneous rupture of the heart, 667.

Clark University. The tenth anniversary of Clark University, 91.

Clarke, A. P. Pelvic tuberculosis, 87.

Clearing House. A hospital clearing house, Blake, C. J., 186.

Cleft Palate. Detail in cleft palate operations, McCurdy, S. L., 67.

Cobb, F. Case of imperforate anus, 6.

Cobb, F. C. Peritonsillar abscess, 81.

Coit, J. M. Liquid air, 114.

Cold wave of February, Hasdale, G., 246.

Comparison. Terms of comparison, 482.

Confidence. The inviolability of professional confidence, 671.

Contract surgeons in the United States Army, Munson, E. L., 588.

Council, J. F. Our consumptives, where to send them, 21.

Coolidge, A. Jr. Removal of a foreign body from bronchial tube through tracheal opening, 205.

Cordier, A. H. Address before American Medical Association, 86.

Coriat, I. H. The phenylhydrazin test for sugar in the urine, 518.

Cothoru, A. M., and Milne, C. J. R. Plague in monkeys and squirrels, 147.

Councilman, W. T. The growth and extension of carcinoma, 256.

Courtney, J. W. A case of ataxic paraplegia developing under circumstances of unusual interest, 449.

Cowles, F. S. Hydrorrhœa gravidarum and hydrosalpinx, 490.

Crandall, F. N. Scurvy in an infant of six weeks, 396.

Cremation, 119.

Crile, G. W. Observations on prevention of surgical shock and collapse based on clinical and experimental evidence, 43.

Crocker, S. E. Excessive crying of infants, 227.

Crothers, T. D. Morphinism among physicians, 525.

Crying. Excessive crying of infants, Crocker, S. E., 227.

Cuba. General Wood's report on provinces of Santa Clara and Santiago, Cuba, 354.

Cumston, C. G. Carcinoma under the age of thirty, 435.

Currie, J. Z. The treatment of post-partum hemorrhage, 489.

Curry, J. J. On the value of blood examinations in the diagnosis of camp fevers, a report of the blood examinations in typhoid fever and in the malarial fevers, 513.

Curtin, R. G. Cardio-esophageal gush and click simulating a heart murmur, 246.

Cushing, C. Cholecystotomy, 87.

Cushing, H. W. The "right-angle" continuous intestinal sutures, 87.

Cutaneous System. Hygienics of the skin, Judd, L. D., 101; the rôle of the staphylococcus in skin diseases, White, C. J., 225;

Hygienics of the skin, Judd, L. D., 344; report on progress in dermatology, Bowen, J. T., 317, 365; epithelioma as a sequel of psoriasis and the probability of its arsenical origin, Hartzell, M. B., 349; two epidemics of alopecia areata in an asylum for girls, J. T. Bowen, 350; literature of the purulent dermatoses and their exciting organisms, Elliot, G. T., 369; results of bacteriological examination of 300 vesicular and pustular affections of the skin, with some inoculative experiments, Gilchrist, T. C., 370; modes of infection of leprosy, Morrow, P. A., 370; remarks on the treatment of scabies, Sherwell, S., 370; a contribution to the study of blastomycetic dermatitis, Hyde, J. N., 371; urticaria of the mucous membrane, Packard, F. A., 396; an instance of urticaria occurring as an initial rash in typhoid fever, Woodbury, F., 519; acute universal eczema with special reference to its etiology, Brownrigg, A. E., 572.

Darling, E. A. The effects of training, 205, 229.

Davenport, F. H. Case of sarcoma of the uterus, 214; the erosions of the cervix uteri, 357, 365.

Davis, N. S. What are the physiological processes or functions that impart to the living human body its vital resistance or immunity to the action of the toxic agents to which it may be exposed; and how can that be aided in the treatment of disease? 13.

Death. Chances of death in war, 534; the right of the dead to live, 670; the natural right to a natural death, 671.

Death-rate of the United States troops in the Philippines, 615.

Denver, J. B. Complications and sequelæ of appendical abscess, 43; indications for an operative treatment of post-puerperal sepsis, 89.

De Sloës, I. A. Fibrolipoma of tonsil, 298.

Deer Island. A new hospital for Deer Island, 171.

Devine, W. H. Improvements in army medical service suggested in the late war, 187.

Delirium. A case of post-febrile delirium, Greenleaf, R. W., 419, 423.

Digestive System. Imperforate rectum, Higbee, F. A., 6; case of imperforate anus, Cobb, F., 6; a case of imperforate rectum, Porter, C. A., 6; the treatment of the abdominal viscera through the colon, Turck, F., 26; chemosynthesis, Stockton, C. G., 39; considerations on the diagnosis and treatment of gall-stones, Ranschoff, J., 42; observations on the treatment of gall stones, McCosh, A. J., 42; appendicitis as a cause of inflammation of the right ovary and tube, Oschner, A. J., 42; complications and sequelæ of appendical abscess, Denver, J. B., 43; diagnosis and treatment of appendicitis, with report of 102 cases, Means, 43; inquiries in the etiology and treatment of appendicitis, Harsha, W. H., 43; operation for undescended testicle and congenital hernia, Bevan, A. D., 44; surgical treatment of acute peritonitis, House, A. F., 46; intestinal fistulæ, Murphy, J. B., 65; some of the rare forms of hernia and their radical treatment, Murphy, J. B., 65; infundibular process in the normal development of the male subject in hernia, Marey, H. O., 65; umbilical hernia, Lord, 66; some complications resulting from rectal operations, Beach, W. M., 66; a typical operation for the radical cure of oblique inguinal hernia, and atypical cases, Ferguson, A. H., 66; phantom semilunar and annular strictures of the rectum, their diagnosis and radical treatment under direct inspection, Martin, T. C., 68; surgical significance of certain physiologic, anatomic and pathologic peculiarities of the peritoneum, Niles, H. D., 92; the treatment of the acute diarrhœa of infancy, Morse, J. L., 101; hernia following operations for appendicitis, Harrington, F. B., 105; intussusception, Munro, J. C., 253; the complete stitch, 257; a case of total extirpation of the stomach, with remarks upon the surgical treatment of gastric cancer, Richardson, M. H., 305; resection of the cecum and a portion of the ileum for carcinoma, Johnson, F. W., 364; gastric ulcer at the Massachusetts General Hospital, 1896-1898, Brewer, Gaylord, Boston, Jr., Pp., 369, 393; examination of digestive cases, Smithwick, M. F., 415; Dr. Brigham's case of extirpation of the stomach, 431; the patient stomach, 458; a brief summary of the indications for operation upon the stomach, Einhorn, M., 499; three cases of pyloroplasty for stricture of the pylorus, Richardson, M. H., 547, 554.

Diphtheria. The official definition of diphtheria, Hill, H. W., 579.

Disease. Not the disease only, but also the man, Putnam, J. J., 53, 77.

Disinfection. Personal experience in disinfection, Johnston, W., 555; experiments upon the disinfection of rooms with formaldehyde gas in the City Hospital at Charlottenburg, Berlin, 593, 619; disinfection and prevention in the sick-room, Harrington, C., 617, 630.

Dispensary. The private dispensary, 94; annual report of the Boston Dispensary, 377.

Doch, G. Use of quinine in malarial diseases, 16.

Donohue, F. O. Progress of the science and art of obstetrics, 490.

Draper, F. W. Clinical abortion with a "dying declaration," 461, 471.

Dreyfus trial *vs.* medical progress, 327.

Dudley, A. P. Impressions of the work of the International Gynecological Congress at Antwerp, 1898, 499.

Eagleson, F. S. Case of pancreatic cyst, operation, recovery, 69.

Ear, Tympano-mastoiditis, Fritz, E., 114.

Eczema. Acute universal eczema with special reference to its etiology, Brownrigg, A. E., 572.

Edes, R. E., and Pearce, R. M. Unusual diastolic murmur with autopsy, 162.

Editorials. The annual dinner of the Harvard Medical Alumni Association, 23; a notable bequest, 94; the Massachusetts School for the Feeble-Minded, 24; annual discourses and addresses, an explanation, 47; the floating hospital, 48; surgical instruments admitted free of duty, 48; tetanus and Fourth of July, 71; the treatment of inebriety, 72; the tenth anniversary of Clark University, 94; the private dispensary, 94; English *vs.* American athletes, 95; the study of tropical diseases, 118; as to cremation, 119; a closer relation between medical progress and the general practitioner, 120; a criticism of the proposed changes in the curriculum of the Harvard Medical School, 143; sanitation in Puerto Rico, 144; accidents and law-suits, 171; a new hospital for Deer Island, 171; the dangers of over-enthusiasm, 173; Prof. Robert W. E. Bunsen, 189; a statistical study of the relation between weather and crime, 201; Rainsford Island, 202; emergency stations, 222; the yellow-fever question, 223; prophylaxis against small-pox, 247; an army sanitarium for tuberculosis, 248; a sign of progress, 249; the report of the pauper institutions trustees, 271; scientific study of physical training, 272; the Boston City Hospital report, 299; a proposed card centralbiatt, 300; report of the International Congress on Tuberculosis, 301; settlement of suits for damages out of court, 326; the Dreyfus trial *vs.* medical progress, 327; progress in military sanitation, 328; the International Congress on Venereal Disease, 350; the scientific study of physical training, 351; uniform requirement for license to practise medicine, 374; improved building laws in New York, 376; a new course of instruction for the army hospital corps, 376; prizes offered by the Massachusetts Association of Boards of Health, 375; an international catalogue of scientific literature, 398; pure-food legislation, 398; the new army ambulances, 399; disease at summer resorts, 426; the report of the Boston Health Department, 427; higher medical education, 453; quarantine regulations, 454; protective inoculation against typhoid, 455; progressive surgery, 478; the nurse as a specialist, 479; Professor Osler's address at McGill University, 502; municipal gymnasiums, 502; annual report of the surgeon-general of the navy, 503; the proposed enlargement of Boston's Insane Hospital, 526; our attitude toward incurable disease, 531; the female nurse in the army, 556; Congrès International Antituberculeux, 559; take no thought for the morrow, 560; a bacteriological and chemical section of the American Public Health Association, 581; legislation for the army medical service needed, 582; Americans and Englishmen as well as Italy, for the Italians, 584; medical inspection against English and American army, 610; the public health and commerce; legitimate and illegitimate quarantine, 611; annual report of the Massachusetts School for the Feeble-Minded, 612; report of the Marine Hospital Service, 636; some results of enthusiasm, 639; prizes as a stimulus to research, 667; spontaneous rupture of the heart, 667; Christmas at the hospitals, 668.

Edson, C. H. A case of septicæmia treated with normal salt solution, 52.

Education. Study and teaching of obstetrics in our medical schools, Root, E. H., 115; a criticism of the proposed changes in the curriculum of the Harvard Medical School, 143; higher medical education, 453; the report and comment of the scientific departments of medical schools, Osler, W., 533; the relations of laboratories to public health, Welch, W. H., 555; university laboratories in relation to the investigation of public health problems and to commercial work, Richards, E. H., 558.

Einhorn, M. A brief summary of the indications for operation upon the stomach, 499.

Murphy, J. B. Intestinal fistulæ, 65; some of the rare forms of hernia and their radical treatment, 65.
Nails. Is nail cutting a surgical operation? 566.
Navy. Annual report of the surgeon-general of the navy, 503.
Nervous System. The Cavendish lecture on the etiology and diagnosis of cerebro-spinal fever, Osler, W., 1, 32; cerebro-spinal meningitis, Miller, T. N., 14; laminectomy with report of cases, Munro, J. C., 46; tetanus and Fourth of July, 74; recent progress in neurology, Knapp, P. C., 108; some post-paralytic deformities and their treatment, Taschner, J., 149; two cases of injury of the cord resulting from fracture of the spine, Thomas, J. J., 233, 242, 259; the treatment of cerebral tumors, Knapp, P. C., 333, 359, 384; porencephalus, case and specimen, Acker, G. N., 368; sarcoma of the cerebellum in a child four years old, Adams, S. B., 369; meningitis due to the typhoid bacillus, Wentworth, A. H., 394; a case of ataxia paraplegia developing under circumstances of unusual interest, Courtney, J. W., 449; a case which baffled diagnosis, Symonds, B. R., 495; the value of operative treatment of spina bifida, Reid, W. B., 499; curability of epilepsy and how it may be accomplished, Spratling, W. P., 525; an epidemic of intercostal neuralgia, Reilly, T. F., 533; loss of knee-jerks in gross lesions of the prefrontal region of the brain, Williamson, R. T., 562; tumor of the pituitary body, Walton, G. L., Cheney, F. E., and Mallory, F. B., 563.
Newcomb, J. E. Adenocarcinoma of the nose, with report of case, 270.
Newell, F. S. An analysis of the cases of eclampsia occurring at the Boston Lying-in Hospital during the last fifteen years, 466, 475.
Newman, H. P. Extirpation of the uterus, its appendages, tumors, etc., without ligatures or retention clamps; demonstration of a new instrument for hemostasis, with a report of clinical cases, 116.
New York. Summer mortality in New York, 174.
Niles, E. D. Practical significance of certain physiologic anatomic and pathologic peculiarities of the peritoneum, 92.
Noise. Street noises, 236.
Northrup, W. P. The teaching of pediatrics, 367.
Nose. Adenocarcinoma of nose with report of case, Newcomb, J. E., 270; the relation of pathological conditions in the ethmoid region of the nose and asthma, Swain, H. L., Ingals, E. F., and Bosworth, F. H., 323.
Nudity. Climatology of nudity, Robinson, W. D., 244.
Nurse. The female nurse in the army, 558; the female nurse corps of the army, 74; hospitals and matrimony, 274; nurse as a specialist, 479.
Obstetrics. Recent progress in obstetrics, Higgins, F. A., 63, 85; study and teaching of obstetrics in our medical schools, Root, E. H., 115; progress of the science and art of obstetrics, Donohue, F. O., 499; some practical experience in asepsis and antisepsis in obstetrics, Ayres, D., 499.
Ogston, A. Address in surgery, 149, 177.
Oliver, J. C. Treatment of popliteal aneurism by excision, 46.
Orthopraxy. Osteo-arthritis of the spine; spondylitis deformans, Goldthwait, J. E., 128, 143; address before the American Orthopedic Association, Townsend, W. R., 140; the forcible correction of lateral curvature, Bradford, E. H., and Brackett, E. G., 140; some remarks on the class method of gymnastic treatment in lateral curvature, Traslow, W., 140; some post-paralytic deformities and their treatment, Taschner, J., 140; congenital deformities of the spine, Thorndike, A., 141; the diagnostic value of radiography in orthopedic and general surgery, Weigel, L. A., 141; pigeon toe, Hopkins, W. H., 141; a study of Pott's paraplegia as affected by correction of the spinal deformity, Goldthwait, J. E., 142; a case of dorsal dislocation of the hip occurring during the course of an acute osteomyelitis of the neck and shaft of the femur, Taylor, W. H., 142; reduction of congenital hip dislocation by the Lorenz method, Wirt, W. E., 142; congenital dislocation of the hip, Sherman, H. M., 142; the kyphotome—a machine for the forcible correction of the deformity of Pott's disease, Taylor, R. T., 166; further observations on the treatment of congenital dislocation of the hip, Whitman, R., 167; cases of tubercular and purulent abscesses of joints treated with carbolic acid, Phelps, A. M., 168; position symptoms in joint disease, Sherman, H. M., 168; some salient points in the treatment of hip disease, McKenzie, B. E., 169; the conservative surgical treatment of tuberculous diseases of the joints, Starr, C. L., 169; Pott's paraplegia as affected by the correction of the spinal deformity; a report of cases, Goldthwait, J. E., 184.
Oschspaz, A. J. Appendicitis as a cause of inflammation of the right ovary and tube, 42.
Osler, W. The Cavendish lecture on the etiology and diagnosis of cerebro-spinal fever, 1, 32; Professor Osler's address at McGill University, 502; clinical diagnosis of typhoid fever, 526; the proper

endowment of the scientific departments of medical schools, 533; a motto for medical students, 535.
Osteomyelitis. A case of osteomyelitis of the femur, Lund, F. B., 547, 551.
Otis, R. G. The value of the tuberculin test in the diagnosis of tuberculosis, 21; notes on tuberculin test, 247; the struggle against tuberculosis, 290, 292.
Ott, L. The spread of diseases in schools and its prevention, 14.
Ovariotomy. Early ovariotomy, its practical necessity, Rosenwasser, M., 115.
Packard, F. A. Urticaria of the mucous membranes, 396.
Pancreas. Case of pancreatic cyst, operation, recovery, Eagleson, J. B., 69; acute hemorrhagic gangrenous pancreatitis, operation on the second and twenty-eighth days, death, Scudder, C. L., 494.
Pantries. Poisonous pantries, Stainthorpe, W. W., 123.
Pare, A. A rare book on surgery, 540.
Paris. Letter from Paris, 252.
Park, W. H. Bacteriology of typhoid fever, 526.
Pathology. Report on progress in pathology, Wright, J. H., 289.
Pauper Institutions. The report of the pauper institutions trustees, 271.
Pease. Pathological specimens, 658.
Peckham, F. E. A study of fourteen hip abscesses, 413.
Perkins, J. Medical testimony on insanity as an excuse for crime; report of a case, 595, 606.
Phelps, A. M. Cases of tubercular and purulent abscesses of joints treated with carbolic acid, 168; advertising, or being advertised, 583.
Philadelphia letter, 402.
Philosophy of sickness, Harrington, T. F., 154.
Physician. The ideal physician, his character and attainments, Robinson, B., 195.
Physiology. What are the physiological processes or functions that impart to the living human body its vital resistance or immunity to the action of the toxic agents to which it may be exposed; and how can that be aided in the treatment of disease? Davis, N. S., 13.
Pituitary body. Tumor of the pituitary body, Walton, G. L., Cheney, F. E., and Mallory, F. B., 585.
Plague in monkeys and squirrels. Cobborn, A. M., and Milne, C. J. R., 147; Haffkine's plague prophylactic, 302; precautions against the introduction of plague into England, 331; fleas and the transmission of plague infection, 457; another medical victim of plague, 614.
Platt, W. B. Medicine as a profession, 29.
Pleurisy. A case of hemorrhagic pleurisy, permanent drainage, recovery, Sears, G. G., 387.
Pneumonia. Symposium on pneumonia, Wells, E. F., 16; the blood in pneumonia, Stengel, A., 17; systemic infection in pneumonia, the complications and the sequelæ, Preble, R. A., 17; the treatment of pneumonia, Hare, H. A., 17.
Porter, C. A. A case of imperforate rectum, 8.
Practice of medicine. Uniformity requirement for license to practise medicine, 374.
Practitioner. A closer relation between medical progress and the general practitioner, 120.
Preble, R. A. Systemic infection in pneumonia, the complications and the sequelæ, 17.
Pregnancy, affections connected with. Recent progress in obstetrics, Higgins, F. A., 63; spontaneous rupture of the body of the uterus during labor, Ingraham, H. P., 86; indications for an operative treatment of postpuerperal sepsis, Deaver, J. B., 89; management of pregnancy complicated with abdominal tumors, Hall, R. B., 92; necessary abortion, Bowers, W. C., 117; the report of a case of puerperal eclampsia with complications, Hill, E. E., 191; an analysis of the cases of eclampsia occurring at the Boston Lying-in Hospital during the last fifteen years, Newell, F. S., 466, 473; the treatment of post-partum hemorrhage, Currie, J. Z., 489; hydrorrhea gravidarum and hydrosalpinx, Cowles, F. S., 499; a case of super-rotation, Wheat, A. P., 521; unlooked-for dystocia in certain multiparæ, Boland, E. S., 654, 664.
Prieto, I. Bacteriological study of yellow fever, 555.
Prizes. Prizes offered by the Massachusetts Association of Boards of Health, 375; prizes as a stimulus to research, 667.
Progress. A sign of progress, 249.
Progressive opinion, 202.
Ptomaine. A case of ptomaine poisoning, Blake, H. G., 463, 472.
Puerto Rico. Sanitation in Puerto Rico, 144; military sanitation in Puerto Rico, 458; a board of examiners in medicine, pharmacy, dentistry, etc., 481.

Address.

THE CAVENDISH LECTURE ON THE ETIOLOGY AND DIAGNOSIS OF CEREBRO-SPINAL FEVER.[1]

BY WILLIAM OSLER, M.D.,
Professor of Medicine, Johns Hopkins University, Baltimore, Md.

In practice we occasionally meet with a meningitis which is not tuberculous, which is not a complication of pneumonia or ulcerative endocarditis, and which is not a sequence of ear disease or of injury, and which is not a terminal infection in some chronic malady. As the meninges of both brain and cord are diffusely inflamed, we label the conditions cerebro-spinal meningitis. At intervals, in certain regions, the cases multiply, and we then speak of epidemic cerebro-spinal fever. Until recently my experience, though somewhat varied, had been confined to a few instances in which the absence of the usual factors justified the diagnosis of the sporadic form of this disease. Within the past year a small outbreak in Baltimore has enabled me to study certain points in the etiology and diagnosis of this most interesting affection, and has thus determined my choice of a subject on which to address you.

I. SUMMARY OF THE FEATURES OF CEREBRO-SPINAL FEVER AS AN EPIDEMIC.

Upon these I shall only touch very briefly.

(*a*) One of the most fatal of all acute diseases, it fortunately takes a very humble position among epidemics as a destroyer. No fever attacks so few individuals in a community during its periods of prevalence; so that the general mortality may be but slightly increased. On the other hand, scarcely any known fever kills so large a proportion of those attacked. The recent epidemic in Boston illustrates this very well. Of 111 cases in three hospitals 76 died, a mortality of 68.5 per cent.

(*b*) The outbreak occurs in certain waves or periods, of which the fourth during the present century is at present prevailing in the United States. For several years there have been local epidemics of the disease in widely separated regions, usually in villages and country districts; but in 1896, 1897 and 1898 a slight epidemic occurred in Boston, and in the latter year cases began to be recognized in Baltimore and other towns. From a recent collective investigation, made under the direction of Surgeon-General Wyman, of the United States Marine-Hospital Service,[2] we learn that cerebro-spinal fever has prevailed during the past year (as a rule, in a mild form) in twenty-seven States, and in the District of Columbia. It is not possible to say that the movement of troops last summer had anything to do with the spread of the disease. The limitation for a year or more to one district or city without spreading to adjacent towns, the localization even (as at present in Washington and Philadelphia) to special districts of a city, the recrudescence for several seasons in succession, are well-known features illustrated by the present epidemic.

(*c*) Among specific diseases cerebro-spinal fever stands in some points close to pneumonia. Sporadic cases of both occur in intervals of epidemic prevalence, though in pneumonia they are much more numerous, while epidemics of pneumonia, like those of cerebro-spinal fever, are most striking in barracks, asylums and jails. Even when not prevailing as an epidemic, there may be remarkable house epidemics of cerebro-spinal fever. The seasonal relations are the same in both, and the two diseases may prevail together. The abrupt onset, the great frequency of herpes in both, the leucocytosis, "the almost identical characters of the fibrino-purulent exudate in the two diseases" (Netter), the frequent complication of pneumonia in epidemic cerebro-spinal fever and of meningitis in pneumonia are additional points of contact. The degree of contagion is about the same in both diseases, and, lastly, it has been claimed that the organism described in cerebro-spinal fever is only a variety or a degenerate form of the pneumococcus.

On the other hand, Leichtenstern, speaking against the view that the pneumococcus is the cause of epidemic cerebro-spinal fever, says: "Pneumonia is a disease spread over the entire earth, and appears at all times, there being no land immune from it. Epidemic meningitis is very rare, and in many countries is still unknown. Croupous pneumonia attacks every age, the disposition increasing somewhat with increasing age, epidemic meningitis is a disease which affects children and young people; beyond thirty-five there is slight disposition to it. Croupous pneumonia has a typical course and a crisis; epidemic meningitis has no crisis. The complications of the two diseases are different, etc." (Quoted by Councilman, Mallory and Wright.[3])

II. BACTERIOLOGY OF CEREBRO-SPINAL FEVER.

Until within the past few years the etiology of cerebro-spinal fever has been obscure, and a majority of observers regarded the organism found in the meningeal exudate as the pneumococcus, or a variety of it. More than twelve years ago, however, Weichselbaum described a diplococcus with special cultural peculiarities, which he regarded as the specific organism of the epidemic form of the disease. Little or no attention was paid to his communication until 1895, when his observations were confirmed by Jaeger. So little notice, indeed, had they attracted that neither Ormerod in "Allbutt's System" (vol. i, published in 1896), nor Latimer in "Loomis and Thompson's System," published in 1897, mention Weichselbaum's organism. The work of Heubner,[4] in Germany, and more particularly the studies of Councilman, Mallory and Wright, have fully confirmed the observations of Weichselbaum, whose organism, known variously as the meningococcus and the diplococcus intracellularis meningitidis, is now regarded as the specific cause of the disease. As the bacteriology of the subject is very fully discussed in the monograph by Councilman and his associates, and in the just issued article by Netter, in vol. xvi of the "Twentieth Century Practice," I shall confine my remarks to an account of our experience in the study of the cases which have been in my wards during the past year. To Dr. Norman B. Gwyn, who has charge of the bacteriological work in my clinical laboratory, and to Dr. N. McL. Harris, bacteriologist in the pathological department of my colleague, Professor Welch,

[1] Read before the West London Medico-Chirurgical Society, June 16, 1899. — From advance sheets courteously furnished by the editor of the West London Medical Journal.
[2] Public Health Reports, vol. xiv.
[3] Epidemic Cerebro-spinal Meningitis. A Report of the State Board of Health of Massachusetts. Boston, 1898.
[4] Jahrbuch für Kinderheilkunde, 1891, and the Deutsche medicinische Wochenschrift, 1897.

I am under special obligations for their careful study of the cases during life and after death.

The meningococcus in cover-slips made from the exudate has usually a diplococcus form, and lies within the polynuclear leucocytes; hence the definition, *intracellularis*. Many of the cells may be stuffed with them. They may also occur free. It stains with the ordinary staining reagents, and is decolorized by the Gram method. It grows best on Löffler's blood serum, on which it forms "round, whitish, shining, viscid-looking colonies with smooth, sharply-defined outlines, which attain a diameter of 1 to 1½ millimetres in twenty-four hours" (Councilman). In cultures it is usually short-lived; but Netter states that Germano has found that it resists desiccation, and has preserved its vitality to the end even of 90 days. He states also that Neisser has shown that the organism is transportable by atmospheric currents, even the most feeble, and that it is very susceptible to aërial convection. It is found in the cerebro-spinal exudate, rarely elsewhere in the body; but it has been isolated from the blood, the pus from the joints, the pneumonic areas in the lungs and the nasal mucus.

The organism is feebly pathogenic for animals. Rabbits and mice resist subcutaneous inoculation. Huebner, and Councilman and his associates have produced typical meningitis by inoculating cultures of the meningococcus beneath the spinal membranes of goats.

Our clinical and pathological experience with the organism is as follows: In 21 cases which I have seen, the lumbar puncture was made in 16. In three patients seen in consultation the diagnosis seemed so clear that lumbar puncture was not made. In Cases 1 and 2, both mild, the puncture was made, in one on the seventh day, in the other on the sixth; but no organisms were found. Cases 3 and 4 were admitted late in the disease, and it was not thought necessary to perform it. Of the remaining 14 cases, in 13 the diplococcus intracellularis was present on cover-slips and in cultures. In the remaining case its presence was doubtful on the cover-slips, and the staphylococcus grew in culture. Of the cases which came to autopsy, five in number, the bacteriologic results, as given by Dr. Harris, are as follow: Autopsy No. 1,104; meningitis, meningococcus; the pneumococcus from a pneumonic area in the lung. No. 1,189, a case with extensive arthritis, in which the diplococcus intracellularis was found in the blood and joint tissues during life, as well as from the meninges. Post mortem, the meningococcus was separated in pure cultures from the cord and brain, and from the lung the pneumococcus and the bacillus lactis aërogenes; from the blood in the coronary arteries the pneumococcus. The other organs were sterile. In Case 10 (Autopsy No. 1,247), on which laminectomy had been performed, the spinal meninges at the time of his death (about two months later) were perfectly normal. At the operation, the staphylococcus pyogenes grew from the culture. In No. 1,314, a case in which laminectomy was performed, the meningococcus was isolated from the meninges, both during life and after death. The bacillus coli communis, the bacillus lactis aërogenes, and the staphylococcus pyogenes albus were also isolated; from a broncho-pneumonic area in the lung the pneumococcus and the staphylococcus pyogenes aureus, from the spleen the staphylococcus pyogenes citreus, and from a thrombus in the superior longitudinal sinus and from the pelvis of the left kidney the streptococcus septicus liquefaciens (Sternberg). This case had a diphtheritic and hemorrhagic cystitis. No. 1,364, a very protracted case, in which death occurred in the twelfth week, and from which the meningococcus had been isolated from the spinal fluid twice, from the meninges post mortem the streptococcus pyogenes and the bacillus coli communis were isolated; and the staphylococcus pyogenes aureus and the bacillus coli communis from the broncho-pneumonic areas in the lungs. In a fatal case outside the hospital, the meningococcus, the pneumococcus and the bacillus coli communis grew in cultures from the cerebral meninges. There was no focus of pneumonia in the lungs.

The following memoranda by Dr. Harris are of interest:

Cultural methods employed. In the first cases we followed the method recommended by Councilman; namely, the use of blood-serum "slants." Such was found to be almost useless on account of contaminating organisms, for, out of a series of eight tubes, only one gave pure cultures.

In the other cases the exudates and fluids were plated out in alkaline five per-cent. glycerin-agar. This procedure gave entire satisfaction, in that the growth of the meningococcus was quite vigorous, and that associated organisms in the exudate (Cases 1,314 and 1,324A) were readily separated and classified.

Upon certain points our observations agree with those mentioned in Councilman's article.

(*a*) We have never seen, as Jaeger states, a capsule formation, nor in any case unassociated with other pyogenic organisms were we able to stain the specific organism by Gram's method.

(*b*) The cases coming to autopsy at the height of the disease furnished upon cover-slip and culture abundant evidence of the presence of the meningococcus, whereas cases which succumbed late in the disease yielded feeble results, or, as in Case 1,364, no evidence at all.

(*c*) The biological features of our several cultures gave practically the same results as Councilman obtained, except that in a few cases, after carrying the organism through several generations, litmus milk was found to be slightly bleached, but with no evidence of acid formation.

Regarding potato-culture, Councilman's statement of an invisible growth on this medium should be expanded by remarking that microscopic preparations invariably show evidences of moderate increase, and that the organisms are much larger than on ordinary media.

At no time has a blood-serum culture been observed to bear any striking resemblance to a growth of pneumococcus on a similar medium.

As in Councilman's experience, great variations in viability of the organisms were noted. But it is worthy of mention that when there is condensation water in the tube and growth present in it, the organisms as a rule will be found to be alive many days after life has ceased in the growth upon the surface of the medium.

Staining Reactions. — Supplementary to Councilman's remark upon focal staining points when using methylene-blue, it might be said that if old Löffler's methylene-blue solution is used, the coloration of that focal point is a decided violet-blue.

Animal Experiments. — Subcutaneous inoculation in rabbits and mice (white and gray house-mice) was resisted in every case.

In rabbits inoculated below the dura mater, or into e ventricles of the brain, death occurred in all within fourteen days to six weeks, and in no instance were we able to find evidences of gross pathologic lesions, nor the presence of the meningococcus on cover-slip or culture. The animals were all greatly emaciated.

Mice inoculated into pleural or peritoneal cavities died in from three to four days, in most cases with general septicemia.

Special Remarks. — Regarding Jaeger's observation of the occurrence of chains of cocci in exudate or spinal fluid, it may be said that it has not been observed, but on blood-serum growths it was quite common to find chain-formation with the unstained light line of cell-division running parallel to long axis of chain. However, this feature is not by any means uncommon amongst the pyogenic staphylococci.

Attempts to isolate the specific organism from any other site than the spinal fluid, and the meninges of spinal cord and brain, have in every case been attended with failure. This is especially noteworthy in Case 1,189, which presented arthritis. A large quantity of the sero purulent fluid was inoculated, incubated for three days, and the plates were found sterile, and yet cover-slips of the fluid showed considerable numbers of intracellular diplococci. The heart's blood of this case failed to give positive results at autopsy, although during life the organism had been isolated from the blood as well as from the joint lesion.

Pneumonic or broncho-pneumonic foci have always given the pneumococcus, either alone or with the pyogenic staphylococci.

One Case, No. 1,314, brings out a possible source of error in the use of Gram's stain upon the cover-slip preparations of the exudate in cases where a secondary infection may be present. The cover-slips from the meningeal exudate in this case were examined by Gram's method before cultures were ready, and cocci were found which did not decolorize, thus causing some surprise, but it was cleared of doubt by finding the staphylococcus pyogenes albus in association with the meningococcus upon the agar-plate.

Case 1,325 A is most interesting in that from the exudate on the cerebral meninges the meningococcus, the pneumococcus and the bacillus coli communis were isolated, and positively identified. A mouse was inoculated intrapleurally with 3 cubic centimetres of a twenty-four-hour-old blood-serum condensation-water growth, and succumbed upon the third day with a general infection.

Another mouse received 5 cubic centimetres of a strong suspension in Durham's medium of a twenty-four-hour-old agar-agar culture of the pneumococcus, but showed no evidence of illness. The milk culture of this organism when stained by Welch's capsule stain exhibited well-defined capsules and stained by Gram's method.

Microbic Association in Cerebro-spinal Fever. — Councilman, Mallory and Wright state that "Mixed infections with other organisms were not uncommon. The pneumococcus was found seven times, once in connection with Friedländer's bacillus. Terminal infections with staphylococci and streptococci were occasionally found."

Netter refers to this point in the following terms: "In a very small number of cases observers have reported finding at the same time with the pneumococcus or the diplococcus the staphylococcus pyogenes, the streptococcus, the colon bacillus, the bacillus proteus, and the capsulated bacillus. These microbic associations are always secondary, however, and we must refrain from regarding any but the two agents above described as the primary causes of cerebro-spinal meningitis."[1]

In the report on the bacteriology of the post-mortems by Dr. Harris, the frequency and number of microbic associations will have been noticed. Three points are of interest in this connection: In chronic cases, as 10 and 17 of our series, the diplococcus intracellularis may no longer be present; we have obtained it, however, for the first time on the 25th, 31st, and 41st days of the disease. Of the two cases referred to, No. 17 presented a most typical picture of the disease, and the diplococcus intracellularis was obtained in the spinal fluid on the 31st and 35th days. At the autopsy the meninges showed a moderate amount of exudate, and there was fluid (purulent) in the posterior horns of the ventricles. The diplococcus intracellularis was not found, but the streptococcus pyogenes and the bacillus coli communis were isolated from the meninges.

Case 10 is of particular interest, and I give here a brief summary of the history.

A sailor, John F., aged twenty-five, was admitted October 29, 1898. The illness had begun on October 26th, with swelling and pains in the right ankle, and the next day the left ankle became swollen, and then the right hip. He was able, however, to walk to the hospital. On admission there were also redness and tenderness of the left wrist. For the first week we were very doubtful as to the nature of his trouble. The temperature was between 102° and 104°, and we rather suspected typhoid fever. On the 31st he complained of pain in the back and hips, and on November 1st it was noticed that his head was in a very retracted position. On November 4th he had retention of urine. On the 6th it was noticed that he could not move his legs. Lumbar puncture was then performed, and two drachms of a thick creamy pus removed which showed cells and numbers of diplococci, some in cells, but a majority free and in groups. Dr. Cushing performed laminectomy, and drained away a large amount of purulent exudate, and irrigated the spinal meninges with normal salt solution. Cultures made from the fluid obtained by the lumbar puncture and at the operation grew the staphylococcus pyogenes aureus. From the history and symptoms the case was doubtless one of cerebro-spinal fever, subsequently affected with the staphylococcus.

More frequently the pneumococcus has been found in association with the diplococcus intracellularis. In our series it was present only once (Case 13) in the fluid obtained by lumbar puncture. On the 5th day 20 cubic centimetres of a faintly cloudy fluid were removed, and both organisms grew in culture. On the 7th day the pneumococcus was isolated from the blood. Netter found the pneumococcus associated with the diplococcus intracellularis (post mortem, I take it, though it is not so stated) in 10 of 16 cases of cerebro-spinal meningitis.

The third point is the occasional association of the tubercle bacillus with the diplococcus intracellularis, but so rarely that it is not a point of much practical importance.

On the whole, then, our observations support those of Weichselbaum, Jaeger, Heubner, Councilman and others, that in epidemic cerebro-spinal fever there is an organism with special cultural peculiarities which may reasonably be regarded as the exciting cause of the disease. Netter alone, among recent observers, seems to doubt this, and says that he only found the diplococcus intracellularis in 16 out of 39 cases, and in 10 of these the pneumococcus was present at the same time. His most recent statement in the "Twentieth Century Practice" (1899) is worth quoting: "Certain observers, and more particularly Jaeger and Heubner, believe that the diplococcus intracellularis is the sole pathogenic agent in epidemic cerebro-spinal meningitis, and that the pneumococcus has no influence whatever in the production of true epidemic meningitis. Councilman is a little less emphatic, although he appears disposed to adopt this way of thinking. I do not, however, in any way accept this view. The pneumococcus can, without any doubt, cause meningitis, and in spite of Heubner's experience, the rôle of the pneumococcus has been most surely established experimentally. The frequent occurrence of

[1] Twentieth Century Practice, vol. xvi, p. 123.

pneumonia complicating meningitis and of meningitis complicating pneumonia, and the coincidence with meningitis of many other inflammations which may be excited by the action of the pneumococcus, imply that between pneumonia and meningitis there exists a relation which cannot be denied." He seems to think that the diplococcus intracellularis may be a degenerate form of the pneumococcus, and in support of this view cites: "Its intracellular position is evidence of a phagocytosis going on, the impossibility of cultivating most of the individuals, as shown by the small number of colonies obtained, its decolorization by Gram's method, and its usual innocuousness in animals. I would not, however, insist upon this opinion, nor lay too much stress upon the arguments just mentioned, for the question is only hypothetical as yet."

It does not seem to be altogether clear, from certain of Netter's observations, that he has been dealing with the meningococcus. Thus, in his communication,[6] the coccus which he found in the eight cases was rounded, usually in pairs, sometimes in short chains; at other times capsules were seen. They stained by Gram's method, and in bouillon long chains developed, and mice resisted infection when inoculated subcutaneously. He concludes, from these observations, that the meningococcus is nothing more than a degenerate pneumococcus. Dr. Harris, in a note on this, remarks: "Such conclusions are entirely unwarranted, or if his observations are correctly stated, he evidently had the veritable pneumococcus to deal with, and, by some strange mode of reasoning, concludes that he has the meningococcus in his series of cases, and that it is identical with the pneumococcus, though of a degenerate form!"

Netter's position is most illogical and confusing. Throughout the article in the "Twentieth Century Practice" — in many ways one of the very best in literature — he assumes that the specific disease, cerebro-spinal fever, may be caused either by the pnemococcus or the diplococcus intracellularis. That a primary cerebro-spinal meningitis may be due to the pnemococcus is universally acknowledged; but it is in the highest degree unlikely that a remarkable specific affection, like cerebro-spinal fever, should be caused by two different organisms. Towards the close of the article the inconsistency of this view seems to impress him, for he says certain peculiarities "prevent us from concluding that the two diseases (that is, pneumonia and cerebro-spinal fever) are absolutely identical."

III. DIAGNOSIS OF CEREBRO-SPINAL FEVER.

Meningitis is not always easy to recognize clinically. Mortifying post-mortem disclosures are even more common with it than with pericarditis. The unexpected meningitis of pneumonia, of Bright's disease, and of other chronic affections, teaches us how latent may be the process; on the other hand, who has not in typhoid fever and in pneumonia made a positive diagnosis of meningitis, and has found post-mortem the cerebro-spinal membranes perfectly free. Sooner or later the truth of Stokes's dictum is brought home to each one of us: "There is no single nervous symptom which may not, and does not, occur independently of any appreciable lesion of the brain, nerves or spinal cord." The anatomical classification of leptomeningitis is not very satisfactory, and, as I have stated, there is a great lack of uniformity in the terms employed. The nomenclature of the Royal College of Physicians recognizes four groups — purulent, tubercular, syphilitic, and cerebro-spinal fever. An etiological classification, possible to-day in part, is of necessity incomplete. In the annexed diagram I have made a provisional grouping of the chief forms:

Acute Leptomeningitis.	Primary.	1. Of cerebro-spinal fever.	(a) Sporadic. (b) Epidemic.	Diplococcus intracellularis.
		2. Pneumococcic.	Meninges alone involved or in a general pneumococcus infection.	Pneumococcus.
	Secondary.	1. Tuberculous.		Bacillus tuberculosis.
		2. Pneumococcic.	(a) Secondary to pneumonia, endocarditis, etc. (b) Secondary to disease or injury of cranium or its fossa.	Pneumococcus.
		3. Pyogenic.	(a) Following local disease of cranium or a local infection elsewhere. (b) Terminal infection in various chronic maladies.	Various forms of staphylococci and streptococci.
		4. Miscellaneous acute infections.	In typhoid fever, influenza, diphtheria, gonorrhea, anthrax, actinomycosis and other acute diseases.	Typhoid bacillus, influenza bacillus, diphtheria bacillus, gonococcus, etc.

The acute primary leptomeningitis in a large proportion of all cases follows an infection with the diplococcus intracellularis or the pneumococcus. It will be a great gain if Still's observations (to which I shall refer later) on the posterior meningitis are confirmed. I do not know where Quincke's meningitis serosa should come in an etiological grouping. Of three cases diagnosed as such in our records, in one a micrococcus was isolated, but nothing further is stated as to its identification. It is highly improbable that, as Netter holds, cerebro-spinal fever either in the sporadic or epidemic forms is caused by the pneumococcus. The body of evidence accumulated within the past few years in Germany and America is strongly in favor of the specific relationship of a definite, easily-recognized organism, the diplococcus intracellularis. The pneumococcus may produce a primary meningitis, and pneumonia at certain seasons and in certain regions may frequently be associated with this lesion, but both clinically and bacteriologically this form can be distinguished from the disease under consideration.

While the possibility of the occurrence must be admitted, I have not recognized a primary meningitis caused by the pyogenic organisms[7] or by the tubercle bacillus. The terminal meningitides I have placed among the secondary forms; and, as in the terminal pleurisies and peritonitides, a variety of organisms are found. Even in cerebro-spinal fever the streptococci and staphylococci, always on the watch for a *locus minoris resistentiæ*, may drive out the original foe, as in Cases 10 and 17.

To the secondary forms of meningitis in the table I shall not refer, except to call attention to the importance of the pneumococcus in this group also; nor can I discuss within the limits of this lecture the clinical features of the varieties of meningitis, and must confine my re-

[6] Bull. et mem. Soc. Méd. des Hôp. de Paris, xv, p. 407, 1898.

[7] The case of John Brooks (autopsy No. 1,805) is of interest in this connection. He had an illness of eight weeks' duration, with obscure cerebral symptoms. On admission he had an urethral discharge. At autopsy there was found an extensive cerebral meningitis, with distention of the ventricles and slight meningitis of the dorsal cord. From the exudate and from the urethral discharge streptococci and staphylococci were isolated. The slight urethral secretion might readily have been overlooked, and the case regarded as a primary pyogenic meningitis.

marks to a few special points in the diagnosis of cerebro-spinal fever, and to a consideration of certain sporadic forms of meningitis.

(I) *Certain Features in the Symptomatology of Cerebro-spinal Fever.* — No other form of meningitis presents a symptomatology of the same fulness — general, cerebral, spinal, and peripheral features are present in almost every case. This results in part from the extent of the cerebro-spinal involvement, in part from the very frequent implication of the nerves, and to some degree is a consequence of the very chronic course. I shall discuss only a few of the important symptoms.

(*a*) *Onset.* — In striking contrast to other forms, particularly the tuberculous, cerebro-spinal fever sets in abruptly. Without warning, while at work, or awakening the patient from a sound sleep, comes the pain in the head, etc. This peculiarity may also be met with in primary pneumococcic meningitis; but in the form secondary to pneumonia, and in that which arises in endocarditis, latency of onset in the rule.

(*b*) *Fever.* — There is no constant type of fever in any form of meningitis. In cerebro-spinal fever the pyrexia is very variable, and I have given here a few charts in illustration.[1] There may be no fever at onset. Of our epidemic cases, all had fever on admission.

Irregularity in the fever may be present from the start. There is not a steady rise at first to a fastigium, but even on the third or fourth day the temperature may fall to normal. Chart I shows this extreme irregularity in a two-hour record. The remissions were very pronounced, and the temperature rose to 108° just before death.

In other cases the course is singularly like that of typhoid fever, and for days the two-hour temperature chart may not show a variation of more than a degree. This is well illustrated in Chart II from Case 17. This patient (as shown on the lantern slide) had the facial aspect of a case of typhoid fever. Chart III from Case 13 shows also a very steady fever with but slight remissions to the time of death on the fifteenth day. Chart IV from Case 15 presents a still more marked resemblance to a typhoid-fever curve, particularly in the daily remissions, giving the spiked chart with which we are all so familiar in the third week of the disease. Intermissions, exacerbations, and great irregularities similar to those in tuberculosis are very pronounced in the more chronic cases. Chart V from Case 16 gives the maximum and minimum daily temperature from the twenty-ninth to the seventy-ninth day. It will be noticed how variable is the time of the highest point of daily fever. On thirteen days the maximum temperature was in the morning — an inverse type, to which many writers have referred, in this disease. The exacerbations are better shown in a two-hour record. In Chart VI from Case 15 the intermittent type is shown, but the paroxysms are distinguished from those of tertian malarial intermittent fever by their prolonged course.

In cases of this sort, when chills occur, the picture is very suggestive of malaria, and one can understand why some of the older writers regarded the disease as a manifestation of paludism. The chart of Case 8 is worth a passing comment. After a very steady temperature on the 9th, 10th, and 11th days, the record on the 12th day was normal. On the 13th day there was a paroxysm without a chill, lasting from 10 P. M. on June 19th to 4 A. M. on the 21st. On the 14th and 15th days the temperature was normal. On the evening of the latter the fever rose, and the paroxysm lasted through the 16th day, and at 4 P. M. the patient complained of decided chilliness. On the 17th day no fever. At 10 A. M. on the 18th day the patient had a rigor, in which the temperature rose to 104.5°; the paroxysm lasted more than thirty hours. Then on the 20th, 21st and 22d days he had recurring attacks, two with chills; the one on the 22d, without chill, extended into the 23d day. After this the patient's temperature remained normal, and he recovered rapidly. During these attacks he complained of a great deal of pain in the head and back. The spleen was not enlarged. The blood was examined daily for the malarial parasites, but none were found. And lastly, Chart VII from Case 15 illustrates the relation of the lumbar puncture to the temperatures. After the sixth, seventh and eighth puncture the fever dropped; after the twelfth it rose.

(*c*) *Skin Rashes.* — Various skin rashes are common in cerebro-spinal fever, and form an important feature in the diagnosis. Of 21 cases which I saw during the epidemic, in 13 a skin eruption of some form or other was present. Herpes, of course the most common, was present in 8 cases. A diffuse erythema about the chest and abdomen, and over the joints, was present in 4 cases. Petechiæ were noticed in 8 cases, extensive in only 3. In 3 cases a very remarkable and peculiar rash was present in the neighborhood of the joints, particularly over the extensor surfaces of the knees and elbows, and about the ankles. There was a diffuse, livid erythema of great intensity, on which pupuric herpes developed — a vesicular rash, the individual vesicles of which became filled with blood. As the erythema faded and the vesicles dried, they could be felt as little nodular hemispherical bodies, which persisted for a week or ten days.

(*d*) *Blood.* — A careful study of the blood was made in all of our cases. A leucocytosis was present in every instance. In four the first blood count was made on the third day, and the leucocytosis was 25,900, 14,500, 40,800, and 32,000 per cm. The first blood count was made on the fourth day in four cases, and the leucocytosis was 26,240, 31,800, 19,300, and 7,600 per cm. In only four cases did the leucocytes exceed 40,000 per cm., and the maximum count was on the ninth day in a fatal case, 47,000 per cm. The leucocytosis persists even in the most protracted cases. In a lad who died in the twelfth week of the disease the leucocytes were 23,000 per cm. shortly before death. As a rule there was no special reduction in the red blood corpuscles. In one case a moderate anemia developed, and in the fifth week the red corpuscles were only 3,100,000 per cm. In one case the diplococcus intracellularis was isolated from the blood during life.

Leucocytosis has no special value in the differential diagnosis of the various forms of meningitis. I had an impression that it was not so constant in the tuberculous variety, but Dr. Parfitt analyzed the records in 11 of our cases and found that in only 3 was a leucocytosis absent. The lowest count was 65,000 per cm. Of 8 cases with leucocytosis there were 4 with 20,000 or more white corpuscles per cm. The highest count was in a child aged eight — 24,333 per cm. Altogether the leucocytosis seems not to be so high or so persistent in the tuberculous meningitis.

(*e*) *Arthritis*, or more often periarthritis, much

[1] The charts were not received in time to print.

more common in cerebro-spinal fever than in other forms, was present in two of our cases. In Case 7 the joint lesion came on with great rapidity, and by the fourth day he had a multiple suppurative arthritis, resembling an acute pyæmia. The diplococcus intracellularis was isolated from the pus in the joints. In the other (Case 10) the disease began with arthritis.[9]

II. *Kernig's Sign.* — Described by a Russian physician, and studied in Germany and France, this interesting sign has not attracted the special attention of English and American physicians, though J. B. Herrick, of Chicago, at the last meeting of the Association of American Physicians, spoke of its value. It has been present in all of our cases in which it has been looked for. It is, I think, an old observation that the subjects of protracted meningitis, particularly children, very often lie with the thighs flexed upon the abdomen, and with the legs in a state of partial contracture, so that they are with difficulty extended. To test for Kernig's sign the patient should be propped up in bed in the sitting position, then, on attempting to extend the leg on the thigh there is contraction of flexors which prevents the full straightening of the leg. On the other hand, in the recumbent posture the leg can be fully extended. Many patients with meningitis are not in a condition to sit up, and the test can be equally well made by flexing the thigh on the abdomen, when on attempting to extend the leg, if meningitis be present, the limb cannot be fully extended. Friis found the sign in 53 or 60 cases, and Netter in 45 or 50. It is stated to be present in all forms of meningitis when the spinal meninges are involved. The presence of the sign is no indication of the intensity of the spinal involvement, as it existed in a very marked degree in a recent case of pneumococcic meningitis, in which there was no positive exudate on the spinal meninges, only a turbid fluid. Netter's explanation of the phenomenon is as follows: "In consequence of the inflammation of the meninges the roots of the nerves become irritable, and the flexion of the thighs upon the pelvis, when the patient is in the sitting posture, elongates and consequently stretches the lumbar and sacral roots, and thus increases their irritability. The attempt to extend the knee is insufficient to provoke a reflex contraction of the flexors while the patient lies on his back with the thighs extended upon the pelvis, but it does so when he assumes a sitting posture."

(*To be continued.*)

Clinical Department.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

PAUL THORNDIKE, M.D., SECRETARY.

REGULAR meeting Wednesday, March 8, 1899, DR. J. W. ELLIOT in the chair.

DR. F. A. HIGGINS showed a case of

IMPERFORATE RECTUM.

Robert N., age four days, was brought to the Children's Hospital, November 24, 1891. His general condition was very good, but there was considerable abdominal distention and tenderness. The anus admitted tip of little finger to a depth of nearly an inch and a half, but no fluctuation above could be felt. Dr. Burrell operated immediately after seeing the case. An incision was made backward in the median line from the outer margin of the sphincter ani, extending up on the dorsum of the sacrum. The coccyx and the left half of the sacrum up to the second sacral foramen were excised with bone-forceps. An opening of considerable size was thus obtained with the rectum lying exposed directly in front. The rectal and anal portions of the bowel were seen to be continuous, and the obstruction found to be due to a membranous diaphragm stretched across about two inches above the anus. The anus was dilated, the diaphragm punctured from below, the opening stretched, and the wound sutured. The stricture was dilated with a glove-stretcher every three or four days while the child remained in the hospital. The recovery was uneventful, and the child was discharged from the hospital on the eighteenth day. Now at the age of seven he is apparently perfectly well, and has had perfect control of the sphincter since infancy. This case is, so far as I am able to find out, the first case of imperforate rectum for which the coccyx and sacrum have been excised in operating for its relief.

DR. FARRAR COBB presented a

CASE OF IMPERFORATE ANUS.

It is my wish to very briefly report the following case, because it demonstrated the value of the posterior operation and the long incision, close to the left-hand border of the sacrum and coccyx (the so-called para-sacral incision), when I had failed to find the rectal pouch by the usual median perineal section. Congenital ano-rectal imperforation and its treatment has been reviewed by Matas, of New Orleans, in 1897, and I can only refer to his paper for a complete study of the subject.

A male infant of Italian parents was brought to the Carney Hospital thirty-six hours after birth. It had passed no meconium, and was said to have cried almost constantly and to have regurgitated all liquids given. I saw the child forty-eight hours after birth and operated without delay. It was a large, well-developed boy. The abdomen was moderately distended and tense. The anus was normal in appearance, but the rectal opening consisted of a shallow depression in the skin — no fluctuation or mass could be felt through this depression. The urine passed normally and was free from meconium.

The infant was placed in the lithotomy position with heaters around it; ether, a few drops at a time, well mixed with air, was used to obtain partial anesthesia. A careful and rather prolonged dissection was made in the median line of the perineum, the incision extending from the root of the scrotum to the tip of the coccyx through the anal tissues, and being carried as deep as I dared to go, but no rectal pouch could be seen or felt. From the normal formation of the anus, I had been led to hope that the case might be a simple one, and the rectal ampulla be found just beyond the external skin, but the external appearance was no guide to the situation of the rectum, and the use of a trocar or exploring needle would have done no good and some mischief. Rather than resort to opening the abdomen it was decided to try and find the rectum by the posterior route, being prepared to do resection

[9] A full report of these cases is given in the Boston Medical and Surgical Journal, December 29, 1898.

of the coccyx and, if needed, partial resection of the sacrum. The previous incision was then prolonged along the left border of the coccyx and sacrum to a point nearly or quite as high as the sacrosciatic notch, the infant being held in an exaggerated lithotomy position. By this incision I was surprised to find how the pelvis became accessible. The coccyx bent back readily, and by using strong lateral retractors very good access to the pelvis for the eye and fingers was obtained. The rectal pouch was found high up surrounded by peritoneum. It was not necessary to cut away the coccyx or any part of the sacrum, although this could have readily been done. At the time of the operation I did not know that this long para-sacral incision had been used and advocated by Vincent for this class of cases.

The peritoneum was opened, the rectal pouch was pulled down to the anus and stitched to its margins with fine silk sutures and opened, the peritoneal cavity being walled off above the gauze. Gauze was left in the wound to protect the peritoneal cavity and to check some obstinate, deep, venous oozing. The external wound was sutured, provisional stitches being left where the gauze strands led out beside the rectum, at the anal border.

The child remained in the hospital about ten days and did very well. It was fed on cream mixture and had free and apparently normal movements. The gauze was removed in forty-eight hours and the provisional sutures tied. The external wound united well and without suppuration. The parents insisted on taking the child home against my wishes, and when it left the hospital it was apparently well. On looking up the case some months after, I learned that it had died of "fits" soon after leaving the hospital. I do not think the operation was a cause of this death, for apparently it was successful, and the child's nutrition was good when it was taken home — but, at any rate, the case cannot be shown you to-night.

In conclusion, I want to note a few practical points in the surgery of this class of cases.

The situation of the rectum cannot be determined by the external appearances (unless in those cases in which meconium is discharged through bladder or vagina). A trocar or exploring needle should never be used.

Primary abdominal section should never be resorted to except in those rare cases of delayed operation in which the child's condition is extremely precarious and immediate opening of the bowel is needed.

As a routine method preliminary dissection in the median line of the perineum should be done, using care to cut backward in the median line and not laterally. If this does not reveal the pouch the attack should be by the posterior route, either with or without resection of the coccyx and part of the sacrum. In many cases resection will not be necessary. In almost all cases the posterior route with resection of the cartilaginous bones will be sufficient. Abdominal section is seldom needed, and only as the last resort. The peritoneum can be safely opened from below.

Dr. Conant: If I am not mistaken I saw this case soon after Dr. Cobb operated on it, and can say that when the baby left the hospital its general condition was as good as one could expect in any child of that age irrespective of the operation, and I saw no reason, from what I knew of the case, why it should not go on and perform its functions in the ordinary way. It certainly was a very successful operation as far as the operation itself went.

After seeing the boy we have seen here to-night, and hearing Dr. Cobb's paper, it may seem presumptuous for any one to state that he believes in any other operation than this. I have seen, I think, five cases in all of this trouble, two at the Massachusetts General Hospital, and it was rather an interesting thing that the first abdominal operation I ever did after I was appointed an out-patient surgeon at the Massachusetts General Hospital was done in the house on a case of this sort. I did not then attempt to remove the coccyx or sacrum, and I don't know but what if I had that operation might have been a success. I tried the posterior operation without the removal of the coccyx and sacrum, and as nothing could be seen or felt it seemed wise to open the abdominal cavity and find out where the rectum was, whether wanting entirely or located in some abnormal position. On opening the abdomen there was found to be practically an absence of the rectum, and there was a point about on a level with the promontory of the sacrum which flared off and covered practically the whole brim of the true pelvis. Any attempt at puncture in that region from below without knowing where you were going would have brought you into the peritoneal cavity at once. Having found exactly where the gut was bulging, a trocar was passed into the incision previously made, and in such a way that practically you went into the gut without opening the peritoneal cavity in front or behind. That operation was done the latter part of May or June, and the child lived until the middle of August, and died of cholera infantum. I was impressed by the fact that the opening of the abdominal cavity made but very little difference in the child. There was not a rise of temperature or pulse to amount to anything. The wound healed by first intention; apparently no shock from opening the peritoneal cavity. The bowels were kept open by inserting a glove-stretcher or the finger. I was very much impressed with the ease with which it was possible to locate the exact position of the rectum, or what was left of the rectum, that is, the very uppermost portion of it, and the ability to demonstrate exactly where you wanted to pass your trocar.

I have been interested in collecting 100 cases reported by Cripp and perhaps they will add some light to the subject. His first series of cases were where the operation was for opening the colon in the groin. There were 16 of those cases, with 11 deaths, and yet if you take up most of the text-books on rectal diseases you find colotomy is one of the operations especially urged if the so-called posterior operation is not successful. He had 3 cases of colotomy in the loin, with 2 deaths. Out of 17 cases of puncture 14 died, which you would naturally expect. Unless you know where you are puncturing you probably go into the peritoneal cavity in front or behind. There were 8 cases of removal of the coccyx and resection of a part of the sacrum and 5 deaths. There was an incision in 39 cases and 14 deaths. He had a series of 14 cases where he made a communication between the rectum and vagina; 1 death. Another series of miscellaneous cases, 3 cases and 3 deaths; out of 100 cases 50 deaths. If you analyse those cases somewhat carefully you find the most deaths are in the class of cases in which you would expect to get death, that is, indiscriminate puncture in the operation of colotomy.

I say this because it seems to me a colotomy in a small child is a much more serious operation than simply opening the abdominal cavity, locating the exact position and tapping from below, knowing exactly where you are going. One interesting thing is his series of 8 cases with 5 deaths.

I suppose there is no question that in the smaller number of cases which may be called the more severe ones, there must necessarily be this division of opinion as to whether this anterior operation is more desirable than the posterior one where you take out the coccyx and sacrum. It seems to me there can always be an honest difference of opinion as to the wisdom of the two methods. If the rectum is as high up as in my case it seems to me it would have been almost impossible to have reached the rectum by any operation posteriorly, unless you take out practically all the sacrum. So that it seems to me there can reasonably be a certain class of cases in which this posterior and brilliant operation cannot be a success because you cannot get up to your sac. I believe this posterior operation has a place for itself and should be the first operation to try. If you can reach the gut in this way you can expect to get better results in the long run than where you have to do an abdominal operation, and then have to do what is known as the combined method, because it is extremely difficult in those combined methods to keep the trouble in the pelvis and in the peritoneal cavity entirely distinct, so that the risk of possible infection is very much greater.

DR. WHITNEY explained briefly the mode of development of the rectum, and how from a malformation the condition of imperforate anus could arise. Specimens from the Warren Museum illustrating this were shown.

DR. ARTHUR T. CABOT said that he should fully agree with Dr. Cobb as to the advantage of the posterior (Kraske) incision in providing access to the pelvic cavity. While not having used this incision himself in a case of imperforate rectum, he had employed it many times in cases of cancer of the rectum, and felt that it would afford a most satisfactory approach to the lower end of the bowel in any case where the bowel descended into the pelvis, and would only fail when the pervious portion of the gut ceased above the pelvic brim.

He mentioned a case reported by him years ago, in which the bowel opened into the deep urethra. The patient had already lived many months with his fecal evacuations all passing *per urethram*. An incision made through the dimple in the skin which marked the seat of the sphincter ani, reached the bowel at a depth of about one and a half inches. The rectal wall was drawn down and sutured to the skin in the middle of the sphincter. The result was absolutely satisfactory, and the patient was seen some years later with good retentive power and a sphincter which acted in all respects normally.

In some cases the rectal sac lies too high in the pelvis to be found and properly treated by an incision from below, and in such cases an abdominal incision, as urged by Dr. Conant, is the easiest, safest and, consequently, the best method of learning the existing anatomical conditions. In some cases it may be possible with the knowledge thus gained to so direct an incision from below that it will enter the rectal pouch safely. When this cannot be accomplished, the bowel can be opened and stitched in the abdominal incision.

DR. MIXTER: Dr. Conant referred to a case he saw the other day upon which I operated, and did what one does not wish to do except under exceptional circumstances—I made an inguinal colotomy. The circumstances were such that I think it was the only possible thing to do. The child was three or four days old, a puny little thing, and the abdomen was so distended that the outside of it looked like a big abscess ready to burst. The skin was glassy and red, and the baby was absolutely blue; in fact, Dr. Whitney suggested it was a blue baby. The pressure had almost entirely shut off what little respiration the child had. It was impossible to give it ether, and I was sure I could feel the pouching rectum not far from the skin; so I made a median incision and not finding it, I did what I should not do except in exceptional circumstances — put in the trocar. Nothing came through the trocar, although I am sure it went into the rectum. Then I made a small incision through the abdominal wall, found an enormously distended gut and caught it by a stitch to the abdominal wall. Round on the inside of the abdominal wall, between that and the gut, was packed gauze, an opening made, and an enormous quantity of very sticky tenacious meconium came out. The child did perfectly well, the gauze was removed, feces came through this opening in the side for something like two weeks. At the end of two weeks the child had done well, was growing and eating well, and digesting its food well, and then a block-tin tube passed through the opening in the side could be passed down to the scar in the region of the anus, and a very slight dissection showed the rectal pouch, which was brought down and opened. The child has done well since then, that is, about a week ago. In that case the rectum was closed to the anus.

I have seen two cases interesting in this connection, being of the same origin as these two cases of anus aberrans Dr. Whitney has shown. One of these I operated upon with success. There was an opening from the vagina or vulva back to the middle of the mass of sphincter which could be easily found, and I did an operation like that for ruptured perineum closing the opening in the vagina. That was done two or three years ago, and the child has had perfect control of the bowels since.

I agree with Dr. Cabot that in most cases the preferable operation would be this lateral operation if it can be done. In certain cases, as in the one I spoke of, it would be impossible to prolong the dissection to that extent. The bowel can be opened from above in less than two minutes without the slightest trouble.

A CASE OF IMPERFORATE RECTUM.

DR. C. A. PORTER reported this case: In June, 1894, I saw, with Dr. Francis Murphy, of Roxbury, a well-nourished boy, two days old. He had not passed meconium. A shallow dimple marked the site of the anus, the levatores and sphincter were normal, Without ether an incision was made exactly in the median line from the penoscrotal angle to the coccyx; the latter was pushed back but not excised, after a long search; dissecting with the forefinger to the promontory of the sacrum, a bulging ampulla was felt, tapped and opened, with free discharge of meconium: The edges of the enteron were brought down and sutured to the skin, and a gauze plug introduced; the whole operation required one and one-quarter hours.

Dilatation with bougies was carried on for two months

with satisfactory results, the bowels moving well; then the mother did not come for several weeks, and finally turned up with the baby in a sad plight. The end of the bougie had broken off and the rough end had been pushed into the bladder through the deep urethra. Most of the urine passed through the contracted rectal scar; much of the feces through the penis. The abdomen was tense and distended; the child very ill, vomiting everything.

Again a long median incision was made under ether; the rectum was reached, and a large rubber drainage-tube inserted into the sigmoid. The baby did well; feces ceased to pass through the penis, but a varying amount of urine passed *per anum*. This condition persisted for eight months, when the mother said urine ceased to escape from the anus; bougies were continued, and again the mother and child were lost sight of.

When the boy was nineteen months old the mother brought him in again; belly distended, scar contracted so that only a knitting needle could be passed up the bowel; feces *per urethram*; urine by rectum once more. A similar operation was performed with rapid improvement.

Examination by Dr. Brewster at the age of two years showed no escape of urine; the little finger could be passed with ease into the sigmoid flexure.

On September 21st, when twenty-seven months old, the boy died of diphtheria in the City Hospital.

Dr. A. Thorndike: One point in connection with the operation I think has not been emphasized, namely, that when you are dealing with a total occlusion of the rectum in these new-born babes you have practically the same condition as in a strangulated hernia, a total obstruction that brooks no delay, but must be operated on at once. I learned this to my sorrow in one case. A child twenty-four hours old came to the Infants' Hospital at nine o'clock at night. I expected to operate, but when I found that the anus admitted the finger about one inch and a half, that the light was poor and the child's condition good, I decided to wait for daylight. In the morning the child was all right; so I pierced a thin occluding membrane a little over an inch within the anus and dilated the opening. There was a copious evacuation of meconium, she took her food well all day and had two movements and was in good shape in the evening, but she died in the night suddenly. No autopsy was permitted. I believe that the longer an imperforate rectum is allowed to remain unoperated the worse it is, provided occlusion is complete. One should, however, be careful to discriminate between complete atresia of the rectum and the condition Dr. Mixter referred to as aberrant anus. They should not be classed together at all, and yet one hears of successful cases of operation for imperforate rectum or anus where a fecal discharge had existed for weeks by the vagina or urethra. We are learning by degrees to appreciate the difference in prognosis between the aberrant anus and the imperforate rectum.

Dr. C. A. Porter: I looked over the cases operated on at the Massachusetts General Hospital in the last fifteen years, and found 15 cases, of which 11 died before they left the hospital. Dr. Conant's case lived two and a half months, another sixty-one, and another twenty-three days, and the rest died within twenty-four hours. In only two cases were autopsies done, one, a case of imperforate rectum, which died from septic peritonitis definitely attributable to three punctures in the rectum through the peritoneal cavity, where the gut was finally found and sewed to the anus.

I should agree with Dr. Cobb that in the majority of cases the median incision behind would reach the gut, but if after fifteen minutes' search the gut cannot be found, one of two operations should be done: the intentional opening of the peritoneal cavity through the posterior incision, or an immediate incision of the left inguinal fossa, which I think gives the child a better chance than a long search through the posterior incision. In one case my father operated on no amount of search in the posterior incision could have found the gut, for there was occlusion of the small intestine in the middle of the ileum, where the gut was adherent to the umbilicus; below that point the whole intestine was much atrophied, though pervious, the rectal ampulla communicating with the anus by a tortuous channel barely admitting a biliform bougie.

Dr. Whitney: If I remember rightly, the bladder is developed from the allantois, which does not come in contact with the rectum, so that in the majority of these cases the opening would be into the vagina or urethra, and the communication of the rectum with the bladder must be extremely rare.

Dr. Elliot: I think the operation done by Dr. Cobb is the proper operation in most cases of imperforate anus. I have, however, had one case of absence of the rectum which was much like Dr. Conant's case. In such cases what is found is that the bowel ends in a great, flaring, blind sac, which fills the top of the pelvis and balloons up and fills the whole abdomen. In such a case — absence of the rectum — where the bowel is glued to the top of the pelvis, a dissection over the coccyx, even with the removal of part of the sacrum, does not reach the bowel. What I found in my case, and what Dr. Conant found, is that you cannot safely open the bowel from below. You feel a large bulging mass above; if you open into it from below you may open the peritoneum or you may open the bladder. The distance is too great for a safe dissection, therefore I think in such cases laparotomy is necessary. Dr. Matas has collected all the cases, and he finds there have been six such cases done where the two routes have been used in combination, and all these cases have recovered. At the time of his paper, however, there were only two cases alive. They died from other causes than the operation. My own case and one other were alive at that time. I think, then, that the reason for opening the abdomen in these cases where the rectum itself is nearly absent, and where the bowel is very high up, is that you may injure the bladder or may open the peritoneal cavity in the wrong place. My case was reported at the American Surgical Association in 1896, and I now have a sequel, which is not uninteresting. The child was two days old, and operated on in May, 1896, at the Massachusetts General Hospital. The coccyx and part of the sacrum were removed, but the bowel could not be reached from below. A laparotomy was done and the abdomen was found filled with the lower bowel distended. That was pushed down until it could be opened through the opening below. When it was opened it collapsed and could be pulled down, and was sewed into the opening by the side of the sacrum, as in a Kraske operation. The child recovered and did very well, but the scar of the artificial anus contracted and was dilated, under ether, in December, 1896. The child was born with a perfect anus, be-

hind which was a blind pouch about one-fourth inch deep, which at the time of the operation I did not molest, as I made my incision entirely above it. In March, 1897, this artificial anus had again contracted so that I had to dilate it; after dilating it I dissected out the bowel from the Kraske wound and found that from the obstruction it had bulged down behind the artificial anus and had worked much lower than at the time of the operation. I therefore pulled it down and sewed it on to the natural anus and that healed, so I had the original relations entirely restored, and the child had moderate control of feces and comfort for the rest of its life. The child died in January, 1899, of nephritis, more than two and a half years after the operation, having grown fat, and having developed fairly well.

DR. WRIGHT: One of the cases to which Dr. Porter has referred came under my observation. The small intestine about midway in its course showed defective development, there being two blind pouches in close apposition to one another, and more or less adherent to the abdominal wall in the neighborhood of the umbilicus. The explanation is not clear. I should be very much obliged if some one would explain, on embryological grounds, how this condition could arise.

DR. WHITNEY: That question is very interesting. There are several specimens in the museum where the small intestine has failed to develop midway in its course. From the adhesions in the neighborhood of the umbilicus mentioned by Dr. Wright it is possible that it is in some way connected with an omphalo-mesenteric condition, and in this case, instead of pulling out the gut, it has pulled it apart.

A CASE OF ACTINOMYCOSIS; OPERATION; RECOVERY.

DR. MIXTER showed a cured case of actinomycosis. This man had in the side of his neck a mass which we thought was an ordinary tubercular abscess, and on removing this thoroughly it was examined by Dr. Wright. I dissected out everything under the jaw, and here is simply the scar, such as you would see in the neck following any chronic abscess. In other words, this is a case of lump-jaw cured. I think it is interesting as showing that this thing can be cured. It was operated in September.

DR. CABOT: How far beyond the visible edge of the disease does the infection actually extend?

DR. WRIGHT: In these cases I have seen and from what I know of the disease I should say it is not an infection which is like anthrax or some of the other infections, in which the extent of the disease is beyond our naked observation. I think one can tell with the naked eye very well how far the infection has spread.

THE PATHOLOGY OF ACTINOMYCOSIS.

DR. J. H. WRIGHT gave a brief account of some points in the pathology of actinomycosis. He considered that the disease is probably more common in man than is generally supposed, and that it often goes unrecognized. He referred to several cases that had come under his observation at the Massachusetts General Hospital during the past two or three years. In two of these the disease was superficial and localized, so as to be readily and radically removed. The methods of diagnosis by means of the microscopical examination of the characteristic granules found in the lesions were explained.

DR. WHITNEY: We had known the disease in cattle, but I think this was the first instance in this immediate locality in which the disease was detected in man. As Dr. Wright has said, it is very often associated with foreign bodies. In this case a fish-bone had apparently perforated through the intestine and was present in the abscess. In cattle it is supposed that portions of wheat or rye are driven into the gum and alveolar process, and this seems to be the favorite locality for its commencement. I think Ponfick first described the lesion in man, and in his cases there were extensive prevertebral abscesses. I have one or two photographs of cases in man of the disease of the face. The general resemblance of the appearances to leprosy or tuberculosis is evident.

DR. MIXTER: I have had two cases, one of which I have shown to-night and the other Dr. Whitney has alluded to. I opened what I supposed was an ordinary abscess, and presently Dr. Whitney said it was a case of actinomycosis. The case was that of a man of sixty with a small mass just above the umbilicus. This I opened and found this peculiar looking pus, and Dr. Whitney found it to be actinomycotic. I excised the whole mass, taking out the umbilicus and portions of the rectus muscle down to the peritoneum and found that the whole thing was adherent to the intestine and had to be separated. I tied off the omentum and cut it away from the intestines so that I left only a little of the mucous membrane and did intestinal suture. Dr. Whitney hardened the mass. The interesting part is that in this mass were these two fish-bones which you see projecting. These had perforated through from the bowel. At the time of the operation I said before I began: "Gentlemen, this looks like a skewer abscess in a dog." Dogs are likely to get skewer abscesses from swallowing wooden skewers. The dog swallows these sharp wooden skewers in pieces of meat and becomes sick, if he does not die. Sometimes on the surface of the abdomen or elsewhere will appear a lump which will break, and out of it comes the skewer and the dog gets well. This thing was suggested to me. It was a perforation by a fish-bone. In this case the actinomycosis probably was not present in the fish-bones when they were eaten, but I suppose some of the actinomycotic tissue was taken into the stomach, and, finding this wound in the intestine, produced this thing. This mass was removed in 1894 or 1895. I had a letter from the man this last week. He said he was perfectly well except the hernia at the site of the operation; it was impossible to draw the wound together. But he is alive and well after four or five years and with this comparatively deep-seated process.

The man you just saw is a patient I saw with Dr. Swan, of Stoughton, and the abscess had been opened and had kept on discharging. It was supposed to be an ordinary tubercular abscess. I took him into my service at the Massachusetts General Hospital, and whether or not at the time of the operation we had the pus examined I have forgotten; at any rate Dr. Wright found these masses. It was a well-marked case and perhaps answers the question Dr. Cabot asked as to how far this disease extends, whether farther than you can see it. I curetted the thing fairly well and began to dissect out the base, and in the outlying tissue I took out where it looked inflamed Dr. Wright found absolutely nothing: it was only in the more softened parts. The thing healed up by granulation and there has not been any sign of recurrence.

Dr. J. W. Elliot reported several

CASES OF ACTINOMYCOSIS.

I have had several cases of actinomycosis in my hospital service. I have had one case like Dr. Mixter's fish-bone case. I opened an abdominal abscess which was filled with a peculiar material, finally a second operation was done and a fine-tooth comb came out in a mass of fibrous tissue. The thing looked different from anything I had seen before; I knew it was not an ordinary abscess, and I have little doubt that it was actinomycosis. I have had three other cases which were proved by the microscope to be actinomycosis, which shows that the disease is not very rare. The first case is the case Dr. Mallory discovered at the autopsy. That case I operated on for necrosis of the rib and I noticed a cavity in the chest full of what I supposed to be tuberculous material. It was packed with iodoform gauze and I never got to the bottom of it. The man finally died at the City Hospital, and Dr. Mallory discovered at the autopsy that it was actinomycosis. Another case Dr. Wright has already referred to — actinomycosis of the liver. I was called to the medical ward to see a man with a very high evening temperature with morning remissions, with evidently trouble in the liver. The liver was enlarged and felt very hard; I thought it might be cancer, but I had never seen cancer of the liver make such violent constitutional disturbance. Dr. Scudder, taking my service, made an exploratory incision, found nothing to attack and closed the incision. Later abscess of the liver developed, pointed and was opened. Dr. Wright made the diagnosis of actinomycosis from what came out, and the patient died practically of abscess of the liver.

The last case is a most interesting one clinically, and in every other way, as the man is now alive. Two years ago when I came on duty I found a man who had been in Dr. Homans's service, but Dr. Homans had not operated on him. He had one of those troublesome sinuses near the anterior superior spinous process of ilium, going down into the abdomen, which all surgeons dread to see because suggesting disease of the sacro-iliac synchondrosis, and that is what I supposed it was. I laid this sinus open and found that it led to an enormous cavity of actinomycosis, which I proceeded to clean out, regardless of its extent. I found everything was mushy near the opening, and I was led on from bad to worse, laying this sinus open deeper and deeper and finding this mushy tissue all over the right side of the abdomen, until before I had finished the operation I had removed the whole abdominal wall on the median line as far up as the umbilicus and out beyond the anterior superior spine down to Poupart's ligament, and up nearly as high as the rib on the side; the whole side of the abdomen was taken away and there must have been nearly a quart of mushy tissue scraped out. The disease was found between the intestines and had made an opening into the small intestine. While we were at work Dr. Wright reported it was actinomycosis, so we went on with more vigor and determination. It had extended all round the iliac artery, which seemed to be the only tissue in the region to resist its progress. We scraped the psoas muscle, took out the appendix and scraped the cecum and finally packed with gauze. The man recovered with fecal fistula, and about six months afterward I found that the disease was not returning deep down, but was returning back in the loin, so we etherized and scraped away another large mass of this disease. This time the scraping started where I left off in the loin and went back into the side. It had invaded the fatty tissues especially. By that time I had learned how the disease looked and could easily distinguish the diseased tissue from the sound. There were almost characteristic little holes of broken-down tissue which at first looked like tuberculosis. We stopped the disease in that direction by deep scraping. He recovered from that, and passed into the hands of Dr. C. B. Porter, and Dr. C. A. Porter has followed up the case and will tell us how he is now. The disease has already lasted about three years and I understand that he is now travelling in Europe.

Dr. C. A. Porter: I have not seen him for nine months. When I last saw him he was out, fairly well nourished, able to eat very well, his bowels moved well, though discharge from the fecal fistula continued. A little while before that visit my father found that the discharge from the granulation tissue still contained actinomyces. He went abroad, not wishing any further operation done.

I will speak of one other case that came to my notice as the result of Dr. Wright's lectures on this organism. I had been searching almost all summer among the alveolar abscesses in the out-patient department for actinomycosis; finally I found one which presented the appearances of an ordinary alveolar abscess which did not open on the outside. On opening the abscess and examining the pus the characteristic appearance was found. I excised the tumor afterwards and there has been no return. The man had broken his jaw six months before, and in all probability the organism entered through the fracture of the jaw and this small tumor developed six months afterwards. The process was quite circumscribed, the walls unusually dense and hard, on section no organisms were found in the granulation tissue, though several small clumps, the size of a pin-head, in the pus were unmistakable.

Dr. Wright presented several photographs of actinomyces showing the branching and general character of the filaments.

Dr. Monks: I have two specimens to show. The first one is a loop of intestine, part of which has been strangulated for eighteen hours. There was nothing remarkable about the case or the operation, except that the bowel was of a dark cherry-red color when strangulated, but, on relieving the constriction, the normal color at once returned. The Halsted method was used for radical cure. Before the man came out of his ether fully he tore off his bandage. Another one had to be put on. The next morning at nine o'clock he suddenly died. An autopsy was held by Dr. Mallory, who examined very carefully all the organs. The only abnormal condition found was edema of the lungs, and this, in the opinion of Dr. Mallory, was the cause of death. Everything about the field of operation was apparently normal. The lung edema may have had some connection with the anesthesia, but this is not certain.

The second specimen was removed by autopsy from a man upon whom I had done an intestinal anastomosis two years and a half previously.

The receipts of the bazaar in aid of the Charing Cross Hospital, London, last week were £13,300.

Medical Progress.

REPORT ON THE DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D., AND A. H. WENTWORTH, M. D.

VALUE OF THE SIGN OF KERNIG IN THE DIAGNOSIS OF MENINGITIS.

NETTER[1] calls attention to this phenomenon, which was first observed in 1882 by Kernig, of St. Petersburg, and which was subsequently confirmed by Henoch, Ball, Blümm and Friis. It is elicited in the following way: The patient is placed in dorsal decubitus, care being taken that the legs are relaxed and fully extended at the knees. When the child is raised to the sitting posture it is found that the knees are more or less flexed, and, despite all efforts, cannot be completely extended on account of contracture of the posterior muscles of the thighs. In some cases the angle made by the thigh and the leg is a right angle, and in no case has it been found to be greater than 135° or 140°. Complete extension becomes possible when the patient is put upon the back again. According to Netter's observations in 46 cases of meningitis of whatever nature, this sign was wanting in but five cases, or about 10 per cent. It has not been observed in other conditions, having been found absent in numerous cases of typhoid fever, pneumonia, acute articular rheumatism, chorea, cerebral affections in infants, erythema nodosum and similar diseases. Netter believes that the presence of this sign confirms the diagnosis of meningitis when the symptoms are obscure, and suggests a latent meningitis when it is the only symptom present. Two cases are quoted. One was a clear case of typhoid fever, but Kernig's sign was present. The patient died of a perforation, and the autopsy revealed the presence of a meningitis due to the staphyloccocus aureus, together with the intestinal lesions of typhoid fever.

A second patient presented Kernig's sign, with slight symptoms of meningitis. Lumbar puncture was made but withdrew no fluid. After a remission of ten days fever reappeared, and a fluctuating mass was discovered over the sacrum. This was incised and the pus was found to contain the meningococcus. The infection had spread from the spinal canal, following the track made by the needle. The presence of meningitis was thereby established. All varieties of meningitis are said to produce this sign, including tubercular meningitis, secondary forms, and cerebro-spinal meningitis.

THE SYMPTOM OF BOLOGNINI IN MEASLES.

A. Koeppen[2] refers to a symptom described some years ago by Bolognini, as existing in measles. This consisted in a peculiar sensation of friction, felt when gently rubbing the tips of the fingers over the surface of the abdomen with gradually increasing force. This phenomenon, which, according to Bolognini, could be felt from the prodromal period well on to the end of the disease, was considered to be due to a morbillous eruption upon the peritoneum, and he considered that it offered a diagnostic sign of measles.

Recently, Koeppen had opportunity to control the observations in the course of an epidemic of measles, during which he specially examined 316 children, several of them on more than one occasion. The symptom of Bolognini was observed in only 154 of these patients. Moreover, the author has been able to convince himself that the phenomenon consists not in a sensation of friction (*frottement*) but rather in a fine crepitation, which recalls that given by subcutaneous emphysema, and seems to be due to the presence of bubbles of gas in the intestines. Indeed, most of the children in whom Koeppen found this symptom were suffering from diarrhea, with foamy stools.

Finally, the author has observed this symptom, though to a less marked degree than in measles, in children suffering from digestive troubles and who were free from measles. In healthy subjects he has never observed the phenomenon.

It follows from these later observations that the symptom observed by Bolognini, although frequently present in measles, cannot be considered as a pathognomonic sign of the disease.

THE SPECIFIC ORGANISM OF VACCINIA.

A. F. Stanley Kent[3] publishes the result of further studies upon the organism discovered by him in the tissues of the vaccine vesicle in 1894. This organism was described as a bacillus, exceedingly minute, measuring a bare micron in length; it appeared to occur, as a rule, in pairs, joined so as to form dumb-bells, not true diplococci. The individual bacilli were very slightly greater in length than in breadth. The bacilli occurred not on the surface, or, as far as could be ascertained, among a variety of organisms which were present in the superficial portion of the vesicle, but were deeply seated in large numbers and in practically pure culture in their special habitat beneath the line of incision.

The author's later studies have been devoted to elaborating a method of preparing pure cultures of this organism; investigating its staining properties; and conducting inoculation experiments with the cultures. He has succeeded in proving that in the organism described as the diplobacillus vaccinia is found a virus which occurs in the vesicles (and tissues surrounding them) of ordinary vaccinia; that this organism has special morphological characteristics and staining reactions. Pure cultures of this organism inoculated into susceptible animals give rise to vesicles which are described as being indistinguishable from the vesicles produced by vaccine lymph. Animals thus injected do not react when vaccinated with active vaccine lymph. Sections through the vesicles thus produced are found to contain the organism in large numbers. These organisms exhibit the same morphological character, staining reactions and distributions in the tissues, as the organisms originally found in the vesicles of typical vaccinia.

THE VALUE OF METALLIC PERCUSSION COMBINED WITH AUSCULTATION IN THE DIAGNOSIS OF PLEURAL EFFUSION IN CHILDREN.

Moussons[4] calls attention to metallic percussion with auscultation (the coin test) in the diagnosis of pleural effusions in children, and considers it a most valuable means in distinguishing between the dulness due to pleural effusion and that depending upon pulmonary consolidation.

[1] Société Medicale des Hôpitaux, July 22, 1898; American Journal of Medical Sciences, February, 1899.
[2] Centralbl. f. innere Medicin, 1898, No. 26, S. 673; American Journal of Medical Sciences, February, 1899.
[3] Lancet, December 17, 1898, p. 1,616; American Journal of Medical Sciences, March, 1899.
[4] Revue Mensuelle des Maladies de l' Enfance, January, 1899; American Journal of Medical Sciences, April, 1899.

The value of the coin test in adult patients in conditions other than pneumothorax has already been investigated by Pitres, and later by his pupil Sieur. Their observations have shown that when the lung is healthy the sound transmitted to the ausculting ear is obscured, smothered, without metallic timbre. In the presence of an effusion in a pleural cavity free from adhesions, the transmitted sound has a clear, sharp, metallic ring.

Congestion of the lung and inflammatory or neoplastic consolidations fail to give the coin test in its purity. The same is true of foci of broncho-pneumonia or of tuberculosis, infarcts, encysted pleurisies and effusions into the pericardial cavity. Not only may the presence of fluid be recognized but the upper limit of the effusion can be detected in pleuro-pneumonia and in pleuritic effusions. The author has devoted several years to the study of this test as applied to young infants, with the hope of proving its value in a class of cases which offers greater difficulties in diagnosis than do similar conditions in the adult. The results have demonstrated to his satisfaction that this test constitutes a very valuable addition to the ordinary methods of diagnosis. He finds that in the young child, as in the adult, the metallic click is muffled and loses its ringing timbre in traversing the healthy lung. The percussion should be made more gently than in the adult, and the non-ausculting ear should be stopped. The same quality in the transmitted sound is to be observed with broncho-pneumonia and croupous pneumonia. In these cases auscultation is made at the point where the vesicular murmur is suppressed or replaced by râles (whether dulness be present or not), the percussion being practised at a point on the hemithorax diametrically opposite. Not only is the sound impure and without metallic ring, but the sound of the stroke itself is enfeebled, and is notably more muffled than on the healthy side; sometimes it disappears altogether. In the presence of pleural effusions the coin test was very clear in four out of seven cases, and in the three remaining cases was clearer than on the healthy side, but lacked the silvery quality.

In six cadavers of young infants, varying in age from a few days to one year, with one of a child of six or seven years, artificial pleural effusions were produced with varying quantities of fluid, and the coin test compared with the results obtained before injection. In no case was the metallic timbre observed before the fluid was injected, while in only two instances after injection did the sign fail. In one of these the sound was clearer, but its metallic quality was not distinct. In both of these cases the test was successful after injecting larger quantities of fluid (above 200 grammes). (When one considers the frequent confusing results offered by physical examination of the chest in young children, even when fluid is present in considerable amount, the value of an additional physical sign, though not absolutely pathognomonic, cannot be too highly estimated. It is to be hoped that more extensive clinical experience will confirm the promises of Monssons's observations.)

THE ANEMIAS OF EARLY INFANCY.

R. Fischl[1] does not believe that it is possible to diagnosticate the nature of the anemias of early infancy by means of the microscopic examination of the blood. His reasons are briefly as follow:

[1] Jahrbuch f. Kinderheilk, vol. xlix, p. 36, 1899; Revue Mensuelle des Maladies de l'Enfance, Mars, 1899, tome xvii.

During the early period of infancy the leucocytes present such polymorphous characters that were they found later in life they would have a pathological significance. No such significance can be attached to them in early infancy.

With regard to the erythrocytes, the great variation in size must be regarded as physiological in the early weeks of life.

Erythroblasts, which exist normally in the blood of the fetus, diminish progressively in number toward the end of fetal life, but small numbers of them are always present in the blood for a short time after birth. The appearance of large numbers of them in the blood of infants indicates abnormalities in the hemapoietic system. In general, the gravity of the anemia bears some relation to the number of erythroblasts in these cases, but this does not permit conclusions to be drawn relative to the nature of the disturbance.

There is no characteristic hematologic picture at this age by means of which one can differentiate anemias. All that can be determined by microscopic examination of the blood is the existence and the severity of the anemia.

It is not possible to conclude from the examination of the blood that this or that part of the hemapoietic system is abnormal, because the organs which take part in the formation of the blood during fetal life can continue to perform their functions to some extent for several months after birth.

On the other hand, the organs which in later life take part in the production of the blood have not reached their complete development in early infancy, and this helps to complicate any deductions which may be made from the appearance of the blood at this time.

The same uncertainty holds good in regard to the number and size of the erythroblasts and their nuclear division; to the appearance of poikilocytosis; and to the polychromatophilic character of the leucocytes. These appearances simply warrant deductions as to the degree of anemia present.

At the present time much of the diagnostic value which was formerly attached to the histological examination of the blood is lost, and it is necessary to search in some other direction for explanations of the blood changes.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

MEETING OF THE SECTION ON THE PRACTICE OF MEDICINE, COLUMBUS, OHIO, JUNE 6, 7 AND 8, 1899.

FIRST DAY.

In a short address the Chairman, Dr. Frank Billings, of Chicago, called attention to the advantages of preliminary epitomes and was inclined to advise that a compulsory abstract be in the hands of the Secretary by the first week in May.

The first paper read was by Dr. N. S. Davis, of Chicago, and was entitled

WHAT ARE THE PHYSIOLOGICAL PROCESSES OR FUNCTIONS THAT IMPART TO THE LIVING HUMAN BODY ITS VITAL RESISTANCE OR IMMUNITY TO THE ACTION OF THE TOXIC AGENTS TO WHICH IT MAY BE EXPOSED; AND HOW CAN THAT BE AIDED IN THE TREATMENT OF DISEASE?

In discussing the subject Dr. Davis touched briefly upon physiologic processes by which the living body maintains its vitality and metabolism in health, how these natural processes are affected by the chief causes of disease, both chronic and acute, and the chief means by which the physician may effectually aid the natural processes in restoring health after disease or disorder has been produced. He strongly advocated the reinforcement of the *vis medicatrix naturæ*.

A COMPARISON OF THE VARIOUS METHODS OF ESTIMATING HEMOGLOBIN

was the title of a paper read by DR. B. M. LINNELL, of Chicago, Ill. The author considered the various color tests, and basing his observations on a number of cases, pointed out the errors of both the Fleischl and Gower instruments. He also spoke of the variations between the different eyes and between the same eyes at different times and under different circumstances. He strongly advocated the approximate estimation by known dilution of the examined blood and considered by far the most accurate Hammerschlag's, or the specific gravity method, in his experience. The normal specific gravity, according to his method, was 1.0605 in healthy adult life. He believed that the variations in hemoglobin were not sufficient to interfere with the specific gravity tests, and also showed a convenient case for applying this method.

In discussion, DR. JUDSON DALAND, of Philadelphia, remarked that there is a certain amount of error in the Fleischel instrument, possible by its delimiting the field of observation and comparison by a perforated cap over the cylinder. He considered the Gower instrument subject to very wide ranges of error and advocated a series of comparative tests by the three different methods.

DR. GEORGE DOCK, of Ann Arbor, Mich., corroborates the testimony as to the efficiency of the Hammerschlag method and condemned the Gower instrument. He described an instrument already on the market similar to that suggested by Dr. Deland, for limiting the field of vision, and recommended an improved pipet, in which definite quantities could be employed. This instrument, however, was very expensive and no better than the specific gravity apparatus.

DR. H. D. ARNOLD, of Boston, directed attention to the importance of the specific gravity method in cases of chlorosis, in which the blood has a very low specific gravity.

DR. LAMBERT OTT, of Philadelphia, then read a paper on

THE SPREAD OF DISEASES IN SCHOOLS, AND ITS PREVENTION.

He contended that most children's diseases are obtained in the intercourse of school life, by kissing, the common use of drinking-cups, the habit of putting pencils in the mouth, etc. The diseases usually spread in school are diphtheria, scarlet fever, whooping cough, measles, varicella and variola or varioloid. To prevent the spread of disease in schools he urged that children convalescent from contagious disease should not be allowed to return to their studies until a certain lapse of time. For diphtheria he fixed four weeks from the inception of the disease, with an additional week in outdoor life, and quite as long a period for scarlet fever. For measles at least two weeks should elapse from the inception of disease, and one week in outdoor life, before the child should be permitted to return to school. Children convalescing from small-pox should not be allowed to return before the expiration of two months from the onset of the disease, and should spend also at least one week in outdoor life. So long as there is a vestige of the symptoms, children convalescing from whooping-cough should be kept away from school. Teachers should be taught to recognize the contagious diseases and by what means they are spread, and children should be instructed in simple rules in hygiene. In all cities there should be a medical superintendent of public schools, and a trained corps of assistants to trace sources of contagion, etc. The author also spoke of the laws of Pennsylvania relating to small-pox and vaccination.

In discussion, DR. ARNOLD, of Boston, described a very successful method of medical examination of the schools in that city by district physicians. He also thought that the period of absence from school prescribed by Dr. Ott was certainly not too short.

DR. J. H. MUSSER, of Philadelphia, considered the subject of such importance that he moved that a committee of three, with Dr. Ott as chairman, be appointed to bring it before the general session, which motion was unanimously carried.

DR. REYBURN, of Washington, believed that a partial remedy for the conditions considered might lie in forbidding children from being sent to school before the age of seven. No child during the period of its most rapid development should go to school for more than one session of three hours a day.

DR. BRAGDON, of Minneapolis, and DR. AXTELL, of Denver, also participated in the discussion.

DR. T. N. MILLER, of Rockford, Ill., in a consideration of

CEREBRO-SPINAL MENINGITIS,

presented the bacteriology and clinical types, the diagnosis and prognosis of this affection, and believed that it was not contagious. He considered symptomatic treatment useless, and hoped for the discovery of antitoxin. He advocated ergot and calabar in the early stages, with perhaps bromides in children. He strongly advised against bleeding, even though it were apparently indicated. Opiates are of great use in all stages of the disease, and the continued use of iodides is advised. Counter-irritation is of value, but he had never used cold application. The best hygienic surroundings should be provided for the patient. The author presented a clinical report of two cases of markedly intermittent type. The infection was evidently through the nasal chambers, and was accompanied by mucopurulent discharge, in which were found large numbers of the diplococcus of intracellularis meningitidis. He gave extensive descriptions of the post-mortem lesions.

DR. C. M. MILLS, of Illinois, spoke of the rheumatic nature of the disease.

DR. J. C. WILSON, of Philadelphia, dwelt upon three points: (1) The importance of Kernig's sign; (2) the isolation of the patient, even though there is evidence to believe that the disease is not transmissible, if it is proven of micro-organismal origin. Certainly any other means of procedure is fraught with danger; it is far better to be on the safe side; (3) the overwhelming importance of opiates in large doses often repeated.

In the discussion DR. DIDAMA, of Syracuse, N. Y.,

gave a history of the successful use of opium many years ago by the advice of Dr. Da Costa.

DR. MUSSER, of Philadelphia, called attention to the value of lumbar puncture as a diagnostic feature and therapeutic measure. It is unattended with danger, is of the utmost importance for early diagnosis, and often gives great relief. He regarded laminectomy as a rational procedure in cases in which there was profound sepsis, or in which there is great pressure. He considered opium the only drug of value.

DR. H. Y. FLETCHER, of Baltimore, had had an opportunity of studying a number of cases in Dr. Osler's clinic and confirmed Dr. Musser's view, but added that although there was evidently relief from the distressing symptoms and temporary prolongation of life, in no case in which lumbar puncture was used did recovery ensue. He called attention to the development of severe arthritis as one of the earliest symptoms, and placed on record the discovery of the causative organism in the joints and in the blood.

DR. SCOTT, of Iowa, spoke on the infectious nature of the disease.

DR. MATHEWS, of Missouri, had never seen evidence of contagiousness in an extensive practice. He believed that in its treatment sodium salicylate should be combined with opium, on account of the analogy of the disease to rheumatism.

DR. BRADWELL, of St. Louis, Mo., had made bacteriologic examination in a number of cases, and with a single exception found the diplococcus intracellularis. In one case he found the micrococcus lanceolatus and he believed this case to be of sporadic nature. He emphasized the importance of Kernig's sign. He found Gram's method of differential staining to be very unreliable.

DR. RABBOLD, of St. Louis, Mo., confirmed the statements of the previous speaker, and spoke of two cases in which there was reason to believe the disease was transmitted. The mortality in St. Louis the last year was 81 per cent. He called attention to the fact that Kernig's sign appears early, and that difficult deglutition was a fatal sign.

DR. ANDERS, of Philadelphia, cited one instance showing the non-contagious nature of the disease. However, he believed in isolation and he considered lumbar puncture as a most valuable diagnostic symptom. He was surprised to find in his consultation practice that almost invariably physicians used ergot instead of opium in treating cerebro-spinal meningitis.

In closing, DR. MILLER reasserted his belief in the efficiency of ergot in the early stages of the disease and opium throughout the course. He also emphasized the value of the iodides.

SECOND DAY.

The following papers were read by title:

"Illuminating-gas Poison," by DR. W. B. HILL, of Milwaukee.

"Have We in Nature a Basis for a Science and Art in Medicine?" by DR. H. J. HERRICK, of Cleveland, Ohio.

"Primary Testicular Mumps," by DR. LANDON B. EDWARDS, of Richmond, Va.

"The Fundamental Principles of Etiology and Therapy," by DR. ELMER LEE, of New York.

"Hodgkin's Disease," by DR. S. E. STEWART, of Topeka, Kans.

"The Vascular Changes in Bright's Disease," by DR. JAMES TYSON, of Philadelphia.

DR. ARTHUR R. ELLIOTT, of Chicago, Ill., read a paper on

TREATMENT OF THE HEART IN CHRONIC INTERSTITIAL NEPHRITIS,

in which he reviewed the cardiovascular changes in granular kidney, and spoke of the friendly offices of the heart in compensating for the diseased organ. He believed that the extrarenal changes were not sufficiently considered in the routine treatment of nephritis. He considered it certainly narrow-minded medicine to focus attention purely on the renal symptoms, and in fact he considered the condition of the heart and blood-vessels sufficient evidence in itself of the renal changes. He dwelt upon the importance of mild exercise by the Scott method to reduce blood pressure. Hygienic and dietetic treatment are of great value. Interference with the circulatory system by drugs when compensation is unbroken is vicious practice. The most important drugs in this disease are aperients and vasodilators. Nitroglycerin is especially efficient and the iodides are valuable. The vasoconstrictor properties of digitalis are especially to be guarded against.

In discussion, DR. R. H. HENRY, of Illinois, believed in the efficacy of mercury and the iodides.

DR. NORMAN BRIDGE, of Los Angeles, said that although theoretically we should expect some direct curative effect from the iodides, clinical experience has not substantiated this thought. He pleaded for investigations to discover a curative agent for interstitial nephritis. He had seen patients die from toxemia before compensation was ruptured.

DR. ALFRED STENGEL, of Philadelphia, set forth that interstitial nephritis was a general disease to be met with by general remedies. He strongly advocated the Scott treatment and believed that the decrease in blood pressure was greater than supposed. The continued use of small doses of mercury is permissible, and he believed sodium iodide is borne better than potassium salt.

DR. WELLS, of Chicago, considered that a reduction of the daily work was necessary, and emphasized the importance of limiting the amount of nitrogenous food.

DR. JENKINS, of Iowa, dwelt upon the importance of nitroglycerin.

A CAUSE AND DIFFERENTIAL DIAGNOSIS OF ACCIDENTAL HEART-MURMURS.

DR. GEORGE W. WEBSTER, of Chicago, read this paper. Every theory or fact in physical diagnosis should be, not the violation, but the realization of a physical law; arguments were given tending to show that no single theory accounts for all accidental murmurs; there is a probability that all accidental murmurs are, like those of organic disease, due to the production of "fluid veins." This may be due to temporary dilatation of the pulmonary artery, relative insufficiency of the tricuspid or the mitral valves, and possibly other causes. The diagnosis rests on: (1) The exclusion of organic disease as shown by (*a*) absence of a history of antecedent casual disease; (*b*) absence of the results of valvular defects as evidenced by hypertrophy and dilatation, or by damaged or broken compensation. (2) By (*a*) history of such disease or conditions as acute intoxications, chorea, the anemias, etc., with which these murmurs are frequently associated; (*b*) the character-

istics of the murmur as shown by rhythm, point of maximum intensity, area of audibility, posture, exercise, etc.

THE TRANSMISSION OF SYSTOLIC MITRAL MURMURS, WITH SPECIAL REFERENCE TO THE NATURE OF THE SO-CALLED ANÆMIC MURMURS.

DR. HORACE D. ARNOLD, of Boston, read a paper under this title. The question of the nature of the so-called functional murmurs has been many times discussed, but the diversity of opinion among the best authorities still leaves it among the unsettled problems. Any contribution to our knowledge, however small, is welcome. The discussion has turned chiefly on the point of maximum intensity of these murmurs — their distribution has not received the attention it deserves. We shall consider mitral systolic murmurs and their distribution; why they are heard at the apex; their transmission to the left from the apex and from the left side of heart; their transmission to the back; systolic murmurs (mitral and others) over the "valvular" area; mitral murmurs in the second left interspace, and their distribution beyond this area; so-called "anæmic" murmurs in the second left interspace and their distribution beyond — similar to mitral; illustrative cases.

DR GEORGE DOCK, of Ann Arbor, Mich., read a paper on the

USE OF QUININE IN MALARIAL DISEASES.

The author dwelt upon the importance of lessening the paroxysms of malaria on account of the disintegration of blood corpuscles. As we have a specific in quinine it is certainly our duty to use it. In this country 15 to 20 grains is usually the daily dose, and in practice it is better to give 15-grain doses at once, or 5 grains at short intervals, followed by 15-drop doses of hydrochloric acid. Small doses repeated several times a day are of avail only in the tonic treatment during convalescence. He advised that the best time for administration was in the stage of decline. For prophylaxis against relapses 10 grains of quinine every five or seven days should be given for several months. He believed that true malarial hemoglobinuria was quite uncommon and that many cases were so diagnosed incorrectly. Of course, quinine should not be used unless there was an absolute diagnosis of malaria.

In an article on

HYPODERMIC USE OF QUININE IN THE TREATMENT OF MALARIA,

DR. G. A. FACKLEY, of Cincinnati, after reporting 20 cases of positive malaria in which he had tried the hypodermic medication, condemned it as being successful in only 3 cases, while in the remaining 17 cases oral administration was successful. He attempted to explain the failure of the hypodermic method by the production of local irritation. He believed that the only indication was when the drug was rejected by the mouth or rectum.

In discussion, DR. STOCKTON, of Buffalo, suggested that as there was a distinct personal variance in the activity of gastric mobility and absorption, there should be no rules for the time of dosage for all persons alike.

DR. DALAND, of Philadelphia, grouped the failures of quinine under two heads: (1) When the drug was not absorbed; (2) when the diagnosis was faulty. He was inclined to believe that the drug should be given during the decline of the paroxysm, and advocated the preliminary use of calomel to further absorption.

DR. F. S. JOHNSON, of Chicago, spoke of the advantages of very deep injections and of the use of quinine by inunction. He gave an interesting case in which the oral method had to be abandoned for the injections on account of accompanying mental delusions.

DR. H. A. HARE, of Philadelphia, regretted that Southern physicians, who had by far the best opportunity to observe malaria, had not done more scientific work in the study of the disease. He dwelt upon the importance of the preliminary hepatic stimulants as by the use of the mercurials and acids. He called attention to the value of blood-examination in differentiating the disease from typhoid fever. He considered hypodermic injections almost useless on account of the precipitation by the alkaline fluid of the tissues, and local inflammation. In its place he would use the normal solution of quinine injected directly in the veins. He spoke of the dangers to the heart of large doses of quinine.

DR. DUNHAM made a plea for the hypodermic injection of the double salt of quinine dissolved in two parts of water, and advised to keep it out of the muscles.

DR. J. C. WILSON, of Philadelphia, in answering Dr. Hare's objection to the hypodermic injection, said that the blood, as well as the rectal secretions, was alkaline, and that although quinine was first precipitated it was afterward absorbed. He preferred the hydrochlorate of quinine, and thoroughly believed in the importance of the hypodermic method in many cases of malaria of long standing.

In closing, DR. DOCK pointed out that the deep hypodermic injections were superior to superficial ones, and that, after all, the method was not generally useful.

The following papers were read by title:

"Syphilis of the Liver," by DR. GEORGE L. COLE, of Los Angeles, Cal.

"Frequency of Subcrepitant Râles in Healthy Chests," by DR. RICHARD C. CABOT, of Boston.

"Traumatic Neurosis Without Ligation," by DR. SIDNEY A. FORD, of Boston.

"The Superstitious Theories and Treatment of Both Extremes of the Century," by DR. ALONZO GARCELON, of Lewiston, Me.

"Treatment of Aneurisms by Gelatine Injections," by DR. T. B. FUTCHER, of Baltimore, Md.

DR. EDWARD F. WELLS, of Chicago, in a general introductory paper covering the field of pneumonia broadly, opened a

SYMPOSIUM ON PNEUMONIA.

He proposed the questions: Is the pneumococcus so often found in the mouth identical with that found in the lungs? How does it enter and what measures may prevent or destroy its virulence? He considered a pulse of 140 a dangerous sign, as well as dyspnœa and the rising and falling of the trachea. He has collected 350,000 cases in which he found the high mortality of 21 per cent. He spoke of the efficacy of venesection in phlethoric persons, and considered that in these cases the procedure had no satisfactory substitute. He also advised a simultaneous subcutaneous injection in the chest of a normal saline solution or

the use of an enema of the solution to replace the quantity of blood drawn. From the beginning to the end of the disease, vasomotor paresis must be met with by strychnia, digitalis and morphine.

THE PNEUMOCOCCUS.

This paper by Dr. Gustav Futterer, of Chicago, Ill., was read by title.

Dr. Alfred Stengel, of Philadelphia, read a paper on

THE BLOOD IN PNEUMONIA.

He limited himself to the clinical examination practical to general physicians, omitting special examinations, such as bacteriology and the estimation of the quantity of fibre in the blood. He called attention to the presence of a chemotactic form of leucocytosis which had an important relation to the diagnosis.

SYSTEMIC INFECTION IN PNEUMONIA, THE COMPLICATIONS AND THE SEQUELÆ.

Dr. Robert A. Preble, of Chicago, read this paper and considered as complications: (1) *Mechanic* plugging of the bronchi; effect on symptoms and physical signs; dilatation of the heart; jaundice; theories of causation. (2) *Infectious:* Septicemia, pleuritis, endocarditis, meningitis, pericarditis, arthritis, miscellaneous mixed infections. (3) *Toxic:* Delirium; renal changes. In the sequels he classed delayed resolutions, nephritis, induration, neuritis, abscess, gangrene.

Dr. Hobart A. Hare, of Philadelphia, read a paper on

THE TREATMENT OF PNEUMONIA.

He believed that the abortive treatment by venesection, aconite, and veratrum viride was applicable only in a few vigorous cases and in the early stage. Heat and cold upon the chest are useful sedatives, and small doses of aconite and opium are permissible. Later on in the disease, venesection should not be used on account of the prolonged after-effect. He advised cold sponging and ice-bags to the head and over the heart. Antipyretic drugs are dangerous, and rarely, if ever, serviceable. As a rule, a failing pulse indicates sedatives rather than stimulants. He believed digitalis was given too often and in too large doses, and often in ineffective preparations. Belladonna was strongly recommended in vasomotor relaxation. He had little experience in suprarenal extract. He cautioned against the promiscuous use of strychnia as a stimulant. It should be used at the proper moment and then heroically. Such substances as alcohol and coca are far better for continuous administration. Nitroglycerin is useful in the aged and when the arterial tension is great; the value of oxygen-gas is problematic.

In discussion Dr. Musser, of Philadelphia, called attention to the fact that pneumonia is a systemic affection rather than a lung disease. Very often, when there is complete absence of physical signs, we have intense symptoms of general infection. He referred to aberrant forms of pneumonia, and called attention to cases in which there was striking simulation of appendicitis. He believed that on account of its insidious onset pericarditis was often overlooked, and remarked on the occurrence of localized areas of intralobar pleural infection. He dwelt upon the value of dry cups in the treatment, and spoke encouragingly of the local application of cold cloths, not only for the local effect but for the relief of the general toxic symptoms. He had never used aconite or veratrum viride and doubted their indication. A most important point is the maintenance of the secretory functions by laxatives, diuretics and diaphoretics. Large amounts of water should be given. In all toxic affections, so long as the urinary secretion is abundant, there is no cause for alarm. He advocated the use of strychnine in emergencies and nitroglycerin in the later stages, but had seldom used digitalis.

Dr. Stockton, of Buffalo, confirmed Dr. Stengel's statements that leucopyemia does mean a fatal issue. He cited an instance of pneumonia of the relapsing type. He did not believe in the use of stimulants if they could be possibly avoided early in the disease, as this prevented their later employment. He believed in large doses of calomel to rid the system of the toxic poisons. When needed in critical cases strychnia is indicated in large doses hypodermically, and so given has saved many lives. He took exception to Dr. Hare's fear of the nervous symptoms so induced and if thought necessary he combated them with opium.

Dr. George Dock, of Ann Arbor, believed in watching carefully the treatment of pneumonia, and added his voice to the value of strychnia and calomel. He believed the local application of ice-bags over the affected parts in previously healthy people far better than the use of the cold bath, and urged more general adoption. Heat does not relieve the pain so well as cold, and poultices are not always efficient, and are very inconvenient. He laid great stress upon the use of the aspirating needle and early bacteriologic examination in the diagnosis of pleural involvement and in forming the prognosis.

Dr. A. M. Holmes, of Denver, mentioned that in Cripple Creek, Colorado, which is in a high altitude, there was great prevalence and high mortality of pneumonia, and it was customary as soon as the diagnosis was made to get the patient into the lowlands.

Dr. J. M. Anders, of Philadelphia, said that a serious phase of this question was the fact that while the mortality of typhoid fever and other infectious diseases has been steadily decreasing, that of pneumonia has been increasing. He strongly advocated bacteriologic examination of the sputum to differentiate between streptococcic and pneumococcic infection; in this way only can the proper use of any antitoxic serum be made. He has found a moderate leucocytosis, as a general rule, and has found that it may persist as long as twenty-four hours after the true crisis. He cited a case of relapsing pneumonia in which neither the pneumococcus nor streptococcus was found in the sputum, and inferred that the rare relapsing cases might be due to some other micro-organism. He approved of Dr. Hare's division of cases into sthenic and asthenic forms, although the former are rare in city practice. He considered moderate bleeding permissible in sthenic cases, and warned against the use of cardiac depressants. In the asthenic cases, he resorted to the hypodermic use of morphia and of the repeated dry cupping. He concurred with the other speakers in the value of strychnine, and believed that when once given it should not be withdrawn abruptly. Turpentine should be accorded a trial in cases of delayed resolution.

Dr. H. B. Favill, of Chicago, dwelt upon the fact mentioned by the other speakers that the disease was a general and not local infection. He believes that

much was to be expected in the future from hydrotherapy.

In closing, DR. WELLS said that while there was no doubt that the dangerous symptoms of pneumonia pointed to general infection, he believed that the disease originated in the lung. He hoped for advances in the field of prophylaxis.

DR. HARE explained that he was clearly misunderstood in regard to his attitude toward strychnine. When it was needed, he believed in heroic doses, but the drug should not be used in small doses repeated for several days. If he could have but two means of combating the disease, he would select the ice-bag and the hypodermic injection of strychnine.

DR. G. BETTON MASSEY, of Philadelphia, made a

FURTHER REPORT ON THE CATAPHORIC TREATMENT OF CANCER.

Cataphoric insertion of nascent salts of mercury in a strength that will deluge interstitially a given tract of tissue or an organ, constitutes a therapeutic procedure of this author. Besides its application in massive dose, generally in association with nascent zinc salts, in the interstitial destruction of the malignant cells or germs of cancer and sarcoma, the method is applicable to the treatment of tuberculosis of accessible portions of the body and to many other conditions where an interstitially-driven germicide will be effective; all ulcerations, cysts, cavities and morbid structures being rendered permanently aseptic by the diffused materials, until perfect healing has been secured. Tissues subjected to the application, whether a small dose has been used or a massive one under ether, show the development of two distinct zones, that nearest the electrode being a zone of total necrosis, around which a line of demarcation subsequently forms, beyond which appears a zone of infiltration reaction, which shows much puffiness and redness for days subsequently, and within which there is evidence that stray malignant cells are killed and the physiologic resisting forces of the body roused. Details are given of cases of sarcoma and carcinoma, ten in all, that have been successfully treated by the method.

DR. G. M. GOULD, of Philadelphia, read a paper entitled

A FALLACY OF THE REST-CURE TREATMENT.

He described three cases which he had treated and in which the general physician or neurologist had ordered the rest-cure without any inquiry as to the existence of eye-strain. A potent and frequent cause of the neurasthenia, hysteria, denutrition, etc., of patients needing the rest-cure, is eye-strain, the symptoms of which are frequently not traced to the true cause and which is thus ignored in the treatment. Mydriasis in such cases, continued for a time, would not only prove a certain means of differential diagnosis, but as good a method of cure as the rest-cure itself.

In discussion, DR. MASSEY, of Philadelphia, took exception to the assumption that neurologists considered the rest-cure the proper treatment for neurasthenia.

In an article on

THE MEDICAL TREATMENT OF MOVABLE KIDNEY,

DR. ALFRED STENGEL, of Philadelphia, confined his remarks to medical measures for restoring the displaced organ. He considered two plans of treatment: (1) Overfeeding, to restore the necessary perirenal fat, which, however, was usually unsatisfactory. (2) The artificial support by an abdominal belt and pad. Most pads are improperly made. They should be so constructed as to exert pressure upward, backward and to the right, instead of directly upward, as is usual. The pad he uses is of kidney shape. He cited cases in which such a pad produced great relief.

In discussion DR. STOCKTON, of Buffalo, said that in thin persons with movable kidney and enteroptosis overfeeding was impracticable. As a rule a pad is unnecessary, often a bandage is sufficient. He suggested the addition of Swedish gymnastics to Dr. Stengel's plan of treatment.

ACUTE ENDOCARDITIS.

DR. W. A. NIELSON, of Milwaukee, read this paper.

The Nominating Committee made the following selections which were favorably acted upon by the section: For Chairman, Dr. George Dock, of Ann Arbor; Secretary, Dr. H. Y. Futcher, of Baltimore.

THIRD DAY.

DR. GEORGE BOODY, of Independence, Ia., read a paper on

TWO EPIDEMICS OF TYPHOID FEVER IN THE IOWA HOSPITAL FOR THE INSANE.

The author concludes that cases of inverted typhoid fever are comparatively rare. In two epidemics recently reported it occurred but once in 43 cases. Of the patients recovering from the aforesaid epidemics, 25 per cent. showed marked improvement in nutrition and muscular strength, while the remainder only reached their former condition, which it seems is a peculiarity in insane patients. Those who improved mentally showed a corresponding improvement in nutrition, which when the mentality returned to normal was remarkable. The author presents these cases as examples of the influence of the mind over nutrition and assimilation. Of the cases reported, nearly 17 per cent. all (afflicted with dementia) improved mentally but seemed to relapse, except in one case in which the improvement was somewhat prolonged; nearly 3 per cent. (afflicted with melancholia) made partial recovery, 5½ per cent. regained their former mental status.

A QUARTER OF A CENTURY'S EXPERIENCE WITH TYPHOID FEVER, WITH SPECIAL REFERENCE TO SOME UNSETTLED PROBLEMS.

DR. JAMES L. TAYLOR, of Wheelersburg, Ohio, read this paper. The author presents a contrast between accredited scientific opinions concerning typhoid fever as advocated formerly and those generally received to-day; how typhoid has displaced marsh fevers; different epidemics characterized by different types of the disease; the varying forms of typhoid; can the radically different types assumed in different epidemics depend on identical causes? Points of similarity between epidemics of typhoid and those of cerebro-spinal meningitis; greater severity of former typhoid epidemics; propagation of certain typhoid epidemics sometimes toward the source of streams instead of toward their mouth; in farming districts typhoid spreads without any possible dependence on water supply; rôle of Eberth's bacillus — some confusing effects of bacteriologic research; practical value of Widal's and other

tests; an anomalous form of typhoid occurring since the influenza visitation of 1889; what points are of most value in determining prognosis.

DR. ALFRED C. HAVEN, of Lake Forest, Ill., read a paper on

A NEW BATH FACILITATING HYDROTHERAPY IN PRIVATE PRACTICE.

He gave a brief history of hydrotherapy, with the reasons for its use and prejudices against it. He has devised a new bath for use in private practice which consists of a canvas strap encircling the headboard of the bed, the ends of the canvas belt fastened by a simple catch so that the belt can be drawn taut. Another canvas belt of similar design is applied to the footboard, there are two rings in each canvas strip twenty-six inches apart; the water is contained in a rubber sheet, hemmed at both sides, in which slip ropes containing four snaps on their ends. The patient is rolled on the sheet, the snaps are caught in the rings and the tub is ready for the water. It is emptied by lowering one corner and completing by a rubber hose syphon. In his judgment such a portable apparatus leaves the practitioner no excuse for neglecting such a potent therapeutic means as hydrotherapy.

DR. L. B. ROUSH, of New Haven, W. Va., read a paper on

THERAPEUTIC PRINCIPLES IN THE TREATMENT OF TYPHOID FEVER,

in which he stated that he considers that certain agents have a somewhat specific influence in lessening the serious effects of typhoid fever. He prefers to institute a moderately free catharsis, especially with calomel, although other cathartics may be used. The course is continued for the first six or eight days and changes the character of the stool; by it the toxemia is in a measure prevented and the symptoms greatly mitigated. In the further progress of the disease ammonium or sodium salicylate is given in solution of five-grain doses every two hours, day and night, throughout the course of the fever, unless the evening temperature falls below 102°, when the medicine is discontinued during the night. Sponging with water is necessary, the temperature of which he regulates according to the patient's feelings. Water and fruit juices should be freely administered; by far the best means of nourishment is milk, although it does not always agree with the patient. He believes that in most cases properly treated patients should get up rather than use the bedpan. Tympanites is considered evidence of continued multiplication of the typhoid bacilli and every effort should be made to avoid it. Catharsis, strychnine internally and turpentine stupes externally are to be preferred. The author claims that with his methods of treatment he has only had a mortality of 3½ per cent. in 143 cases.

DR. E. C. BRUSH, of Zanesville, O., read a paper on

THE USE OF ACETANILID IN TYPHOID FEVER.

The cases reported are those of soldiers sent home last August and September from Camp Geo. H. Thomas, Chickamauga, Ga. They were treated in the Zanesville hospital. The only antipyretic used was acetanilid. The rule in using acetanilid was to give three grains every two hours when the temperature reached 101°. As soon as the temperature fell below 101°, the acetanilid was discontinued. Usually the patient would perspire and the temperature drop from one to two degrees after the second dose. A third consecutive dose was not needed often. The shortest course of the fever was twenty-four days, the longest thirty-five, with an average of thirty days. Only one case was fatal, death occurring in the fourth week from intestinal hemorrhage.

In discussion, DR. WITHERSPOON, of Nashville, said that he believed that in Tennessee the fever is of different type, the temperature coming on suddenly without any period of incubation, accompanied with great prostration, the skin being moist rather than dry. There is general abdominal tenderness, the scaphoid belly and constipation rather than a mushy diarrhea, the fever runs a rather low and favorable course, there is no enlargement of the spleen or liver and the nervous symptoms are those of mild mania. He did not agree in the belief of the efficacy of purging and considered repeated administration of large doses of calomel very bad treatment on account of the risk of increased inflammation and ulceration of the intestine, the purge encouraging a rapid slough. The danger in the disease is from the toxic effect on the nervous system. The Brand treatment not only lowers the temperature but acts as a nerve tonic; acetanilid and other coal-tar derivatives are not safe on account of their effect on the vital resisting power of the patient.

DR. MILLS, of Illinois, said that he has been in the habit for many years of treating typhoid with turpentine emulsion and the other methods laid down by the late George B. Wood, of Philadelphia. He believes that very often there was a combination of typhoid and malaria, both of which must be treated to ensure success.

DR. CROOK, of Tennessee, remarked that his treatment of typhoid fever was directed along the principles of caring for septic wounds, namely, drainage and antiseptics.

DR. BISHOP, of New York, believes that the employment of cold baths eliminated the toxins; he expressed his belief that an efficacious antitoxin was not far distant.

DR. CHARLES G. STOCKTON, of Buffalo, N. Y., read a paper entitled

ACCIDENTAL OR SPURIOUS ALBUMINURIA.

He grouped under this heading those cases in which the albumin finds its way into the urine from the pelvis of the kidneys, ureters, bladder and genitalia. He dwelt upon the importance of considering the possibility of accidental albuminuria, and further said that the urine in such cases should be frequently and carefully studied to make sure that the infection was not invading the true kidney structure.

The next number on the program was a paper by DR. C. W. PURDY, of Chicago, entitled

THE QUANTITATIVE AND QUALITATIVE ESTIMATION OF ALBUMINURIA.

This essay was read by DR. A. R. ELLIOTT, of Chicago. The author considered the gravimetric method, Tanret's titration method, with a double iodide of mercury and potassium, with mercuric chloride as an indicator; the time-reaction of Brandberg; the differential-density method of Lang, Hœbler and Bernhardt; Esbach's volumetric method, and his own centrifugal method, giving both volumetric and gravimetric percentages, with error

not exceeding .02 per cent. His method consists in the following steps: precipitation of the albumin in carefully graduated percentage-tubes of 10 cubic centimetres of urine by means of 2 cubic centimetres of 50-per-cent. acetic acid and 3 cubic centimetres of 1–10 aqueous solution of potassium cyanide; after mingling the urine and reagents, the tube should stand for ten minutes to insure precipitation of the albumin; at the end of ten minutes the percentage tubes are placed in a centrifugal machine, the radius of which, with the tubes in position, must be exactly 6¾ inches. The tubes should be revolved for exactly three minutes at a uniform speed of 1,500 revolutions per minute; the tubes are next removed, and the amount of albumin is read off in bulk-percentage, which, by the aid of an accompanying chart, may be quickly converted into percentage by weight and fluid ounce.

In discussion, Dr. Elliott, of Chicago, remarked that cases of nephritis, unaccompanied by albumin in the urine, occurred more frequently than is generally supposed. He referred to albuminuria accompanying gastro-intestinal disturbances, probably of toxemic origin, which caused an irritation of the renal cells and other secreting structures of that organ. In such cases the urine is of high specific gravity, and throws down acid elements. He spoke favorably of Dr. Purdy's method.

DR. H. B. FAVILL, of Chicago, spoke of the importance of this subject in life-insurance examination. Albumin may be absent in positively nephritic persons, and certain other signs should be remembered in determining the diagnosis. When albumin appears in the urine, a microscopical examination should be made to determine whether the origin is renal. Again, albuminuria may be transitory, and not an evidence of disease; he had seen large amounts of albumin and casts in cases of apparent nephritis disappear. In such cases there was a coincidence of a large amount of indican, probably the results of blood changes.

The following papers were read by title:

"Some of the Ways in which X-rays assist in Medical Diagnosis," by DR. F. H. WILLIAMS, of Boston, Mass.

"The Application of the Centrifuge to the Examination of Feces," by DR. C. D. SPIVAK, of Denver, Col.

"The Changes and Diseases peculiar to Old Age," by DR. J. W. BELL, of Minneapolis, Minn.

"Rheumatism: its Etiology, Pathology, and Treatment," by DR. A. A. YOUNG, of Newark, N. Y.

DR. FENTON B. TURCK read a paper on

THE TREATMENT OF THE ABDOMINAL VISCERA THROUGH THE COLON.

The paper embodies the results obtained by a large number of experiments upon dogs and of subsequent clinical observations, all of which go to show that the colon, by virtue of its close proximity and intimate physiological relations to other organs, offers very great advantages for the treatment by means of hot-water lavage. The temperature used in Dr. Turck's colonic lavage is usually high, 55° C. or 131° F., but this temperature was used only after experiments had shown not only that it did not endanger the patients but that it also proved immeasurably more effective than water at lower temperatures. The scope of the paper covers the effect of colonic lavage at 55° C. upon (1) the heart and circulation; (2) upon the blood, producing particularly quite a marked leucocytosis; (3) effect upon the gastro intestinal tract; (4) upon the kidneys; (5) the liver; (6) upon the temperature of skin, stomach and intestines; (7) the pelvic organs; (8) the effect upon elimination, auto-intoxication and general metabolism.

The effects, according to Dr. Turck, are quite remarkable; the paper, seemingly quite complete, deals largely with the technique of the treatment, and many facts were presented, gained from experimental and clinical observations, showing that there is an increase in the number of leucocytes, and increase in blood pressure, and in the production and elimination of urea. Peristalsis of the stomach and intestine increased. It was interesting to note that upon the introduction of water into the colon at 55° C. there is first a fall in the temperature of the stomach of about 1° F., while the skin temperature gradually rises, later a general rise in temperature; upon the introduction of cold water into the colon following the hot water the body temperature returns to normal.

DR. CHARLES G. STOCKTON, of Buffalo, read a paper on

CHOLECYSTITIS.

In this interesting paper the author called attention to the following facts which were observed by him: (1) in a large number of post-mortem examinations gall-stones are found without the history of jaundice, hepatic colic or other liver disturbances; (2) in persons who have died from biliary obstruction there have been found occasionally no calculi in the biliary ducts, but one or two of great size in the gall-bladder, quite too large to engage in the cystic ducts; (3) obstruction of the biliary passages is not infrequently complete without the presence of gall-stones; (4) a calculus is sometimes found in the common duct without jaundice, colic or other symptoms of obstruction; (5) when gall-stones are found, either post-mortem or during other operations, and there have been recent symptoms of hepatic colic and jaundice, whenever they have been searched for, evidences have been found of cholecystitis, angiocholitis, or both. These observations seem to show that gall-stones may be innocent tenants of the gall-bladder; that attacks of colic may occur when gall-stones are absent, or if present too large to engage; that an inflammatory process of the biliary passages is in some way related to attacks of biliary colic. Operative procedure has for its object the cure of the cholecystosis. Undoubtedly in a certain proportion of these cases the inflammation includes the dangerous complications of angiocholitis, hepatic abscess, and peritonitis, which by the intervention of surgical procedures might have been prevented. However, even in cases in which operation is demanded, a carefully considered plan of treatment should be applied, not only to assist in recovery, but to prevent recurrences.

In discussion, DR. FAVILL, of Chicago, reported a case in which diagnosis of a calculus in the common duct was made and the patient operated upon; no stone was found, but a small nodule in the head of the pancreas had caused the obstruction. The speaker did not believe that the distressing symptoms were always the result of obstruction, and in substantiation related a case which presented all the symptoms of stone in the common duct but jaundice. After many months the patient died and post-mortem there was not found any stone, the symptoms likely being due to infection. He quoted a somewhat similar case under his observation

in St. Luke's Hospital, and dwelt upon the fact that physicians should dissociate the colic and icterus, the latter of which he maintained was mechanical.

DR. EDWARD O. OTIS, of Boston, Mass., read a paper on

THE VALUE OF THE TUBERCULIN TEST IN THE DIAGNOSIS OF TUBERCULOSIS.

In this paper the following conclusions are summarized: (1) The tuberculin test indicates early tuberculosis by a general reaction before it can be detected by other methods, with the exception, possibly, of the Röntgen rays. In the majority of cases, doses of from 5 to 10 milligrammes of Koch's orignal tuberculin are sufficient; (2) in these doses no injurious effects occur; (3) established tuberculosis may fail to give a general reaction from doses of from 10 to 12 milligrammes; (4) a similar reaction is given by syphilis in an undetermined proportion of cases; (5) there is a dose not definitely settled with which a non-tuberculous person may react or simulate a reaction; (6) the reaction may be deferred from six to twenty-four hours. The author formulates the following rules to be observed in making the test: (1) Always use the same tuberculin of a standard strength; (2) employ strict asepsis in the injection; (3) make the injections deep into the muscles of the back, arm or leg; (4) beginning twenty-four hours before the injection, a record of the temperature should be kept every two, three or four hours; (5) the test should not be repeated until several days have elapsed; (6) the general reaction may be depended upon in early cases, but in late established cases, if the general reaction fails, we should look for the local.

A FURTHER REPORT ON THE USE OF ANTIPHTHISIC SERUM (T. R.) IN TUBERCULOSIS (FISCH).

DR. A. MANSFIELD HOLMES, of Denver, read this paper. He remarked that in well-advanced cases the serum invariably causes a rise in temperature within from three to six hours. A more or less extensive infiltration of the injection-areas occurs after prolonged use of the serum. A depressing effect is produced, which is relieved by a short period of rest; usually within two or three days the lymphatic glands become tender and enlarged. He considered the advantages of the tuberculin test twofold: (1) It serves as a reliable means of estimating the degree of convalescence; (2) it serves as a safe and positive means of diagnosis when the bacilli are not found. He believes that the study of the blood count is of as great if not greater importance in diagnosis than examination of the sputum. During the good effects of the serum there is an increase of the lymphocytes of the blood. On the contrary, in rapidly declining cases of tuberculosis there is a progressive diminution in the percentage.

OUR CONSUMPTIVES; WHERE TO SEND THEM.

DR. J. F. CONNELL, of Las Cruces, N. M., read this paper. He considered it a great error to send patients to high altitudes when there was fibrosis or fibroid phthisis; such cases should live in moderate altitudes, or even on the sea level. He called attention to Southern New Mexico, where, at an altitude of 3,800 feet, is a valley surrounded and sheltered by mountains, with a rainfall averaging less than eight inches; sunshine 348 days in the year, and a winter that possesses all the necessary qualifications of climate.

SOME STATISTICS UPON SEROTHERAPY IN TUBERCULOSIS, WITH REPORT OF 106 CASES SO TREATED IN 1898, COMBINED WITH A FAVORABLE CLIMATE AND WITH STRICT SUPERVISION OF THE PATIENT.

DR. C. P. AMBLER, of Asheville, N. C., read this paper. He claims that the use of the antistreptococcic serum, in conjunction with the antitubercle serum, has proved but of little use in his hands. The antitubercle serum is indicated in the incipient cases; it is contraindicated in cases of miliary tuberculosis and in cases of extensive softening high pulse, marked emaciation, or decidedly hereditary history. The injections should not be used when the temperature passes a higher point than 101° daily. A summary of 106 unclassified cases is as follows: Cough and expectoration disappeared in 36 per cent. and diminished in 78 per cent.; the bacilli disappeared in 46 per cent. and decreased in 64 per cent.; the physical signs improved in 84 per cent.; the weight improved in 87 per cent.; the vital capacity in 92 per cent.; the temperature and pulse became normal in 72 per cent.; the average time treated was 4.9 months; the average amount of serum used, 77 cubic centimetres, apparently cured, with no relapse, 39 per cent.; great improvement in 29 per cent.; stationary, 6.6 per cent.; worse, 10 per cent.; died, 1.8 per cent. He concluded that, while serum-therapy is still in its experimental state, the results obtained, in incipient cases, justifies its continued employment.

DR. A. F. LEMPKE, of Chicago, reported

CASES OF TUBERCULOSIS TREATED WITH NITROGEN GAS.

In discussion, DR. EDSON, of Denver, called attention to the importance of early diagnosis. He laid stress upon the general depression of health without obvious causes, the patient progressively losing weight and feeling below par. In such cases an afternoon rise in temperature should be specially watched. He believed that the early stages of tuberculosis were often treated for malaria, and he cautioned against sending patients with pronounced pneumonic infiltration to high altitudes.

DR. MINOR, of Asheville, agreed with Dr. Edson, and also emphasized the importance of prophylaxis, which few patients seemed to thoroughly understand; exercises of the respiratory powers of the chest he considered useful. He dwelt upon individualism as a factor, and had confidence in the serum treatment when used as an adjuvant.

DR. ALLEN, of Missouri, and DR. PAQUIN, of Asheville, N. C., also discussed papers.

In closing, DR. MCCONNELL remarked that, in the early diagnosis of tuberculosis, potassium iodide in small doses is of service, as, after the administration of this drug, evidences of inflammation could be found by auscultation which are not present without its use.

In a paper entitled

THE DIAGNOSIS AND TREATMENT OF THORACIC EFFUSIONS,

by DR. LOUIS FAUGERES BISHOP, of New York, the author briefly outlined the results of an elaborate study of thoracic effusions, undertaken with a view to establish the importance of careful search for fluid in pulmonary conditions and in the necessity of early mechanical intervention. Serous effusion may be due

to increase of exudation or deficiency of drainage. The importance of the fluid depends upon its amount, its mechanical aspect, its quality, and how the patient tolerates it. Pus should be treated surgically. The diagnosis of thoracic effusion was considered at length, and the importance of exploratory puncture emphasized, as the classical signs are not to be relied upon. Physicians should carry a sterilized needle in a small bottle of absolute alcohol and reserve it for the particular use of exploratory puncture. He recommended a large Dieulafoy aspirator. He illustrated the importance of free paracentesis, and illustrated by fatal cases the danger of allowing even a small amount of fluid to remain in the chest. Sudden death from pleurisy with effusion may result occasionally from reflex nervous inhibition of the heart, similar to the temporary hemiplegia that sometimes occurs when the pleural cavity has been irrigated after empyema.

DR. WEBSTER, of Chicago, briefly discussed this paper.

The last paper read was by DR. J. E. GILCREEST, of Gainesville, Tenn., on

LA GRIPPE.

The author claimed there was no specific treatment for influenza. To allay the pain and soreness he used rest and free elimination from the emunctories; he at first gave calomel with sodium bicarbonate in doses large enough to cause free evacuations; he found acetanilid or phenacetin, alone or in combination with Dover's powder, useful; for muscular pains he employed sodium salicylate. Complications and relapses must be especially guarded against.

Recent Literature.

The Elements of Vital Statistics. By ARTHUR NEWSHOLME, M.D., F. R. C. P. Third edition. London: Swan, Sonnenschein & Co. New York: The MacMillan Co. 1899.

This volume constitutes the best practical treatise upon the subject of vital statistics in the English language. While the general plan of the work remains essentially the same as that of the two former editions, the present volume forms an almost entirely new book, having been very carefully rewritten, with much added valuable material. Some of the longer and less useful statistical tables in the early editions have been omitted.

The chapter upon corrected death-rates may be commended to the health officers of those large American cities who are fond of quoting crude death-rates of a very low figure, without regard to the composition of the population at different ages, and with quite as little attention to recognized methods of computing populations in intercensal years.

The thorough illustration of the subject of life-tables and the explanation of the methods of constructing them give encouragement to the publication of such tables for such American communities as have a fairly good registration of deaths in conjunction with a quinquennial census.

This book should be in the hands of every health official who has charge of the supervision of the vital statistics of the population of his district.

Text-Book of Anatomy by American Authors. Edited by FREDERIC HENRY GERRISH, M.D., Professor of Anatomy in the Medical School of Maine, Bowdoin College. Illustrated with 950 engravings in black and colors. Philadelphia and New York: Lea Brothers & Co. 1899.

In this new text-book of anatomy the object of the authors has been primarily the production of a book for the student, a book which should make the acquisition of the difficult subject of anatomy as easy as possible, both by the exclusion of a large mass of detail which is not important to a knowledge of anatomy sufficient to serve as a basis for the study of physiology, surgery and internal medicine, and by the systematic and concise, although not too condensed, presentation of the more important and practical portion of anatomical knowledge.

The fact that greater stress than usual has been laid upon visceral anatomy will increase the value of the book to the surgeon, so large a portion of whose work is now concerned with the organs contained in the great cavities of the body, and the thoroughness of the chapter on Surface Anatomy will commend the work to the same class of readers.

The illustrations of the work are in the main characterized by accuracy, and considerable artistic beauty, but their excellence hardly atones for their lack of originality, the majority being borrowed from Testut. It is a pity that in a distinctly American work such as this text-book, the illustrations as well as the text should not have been in the main original.

The method of portraying the origins and insertions of the muscles, original with Dr. Gerrish, is excellent, and is a relief from the continual repetition of Testut's plates.

The chief merit in the book will be found in the descriptive text, which is accurate, concise, and, in our opinion, gives the essentials of descriptive anatomy with less waste of words and better emphasis of important points than any similar text-book with which we are familiar

Maisch's Materia Medica. A Manual of Organic Materia Medica; Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. For the use of Students, Druggists, Pharmacists and Physicians. By JOHN M. MAISCH, Phar. D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. New (7th) edition, thoroughly revised by H. C. C. MAISCH, Ph. G., Ph. D., Professor of Materia Medica and Botany in the Medico-Chirurgical College of Philadelphia, Department of Pharmacy. In one very handsome 12mo volume of 512 pages, with 285 engravings. Philadelphia and New York: Lea Brothers & Co.

As a manual of materia medica, an excellent work in many respects. The work has been brought well up to date and should be of great value to students of pharmacy and to those students of medicine who desire a more extended knowledge of this subject. The lack of consideration of the subject of therapeutics makes it of less value to the majority of medical students. We find that mention is still made of the toxicodendric acid of Maisch, which was proved to be only acetic acid by Pfaff, in 1897, although reference is also made to the true active principle toxicodendrol.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 6, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE ANNUAL DINNER OF THE HARVARD MEDICAL ALUMNI ASSOCIATION.

THOUGH still young in years the Harvard Medical Alumni Association has already come to fill a place of importance in the community, and to be looked to for expressions of opinion on matters of medical progress. Such associations are further valuable in tending to foster loyalty and develop comradeship, qualities which medical men are likely to lose in the details of their individual professional lives.

The meeting this year was one particularly memorable, both from the achievement of the past and the unusually bright prospects for the future. As guest, the Association was fortunate in having Dr. Leonard Wood, who the following day was honored by the University at large with the degree of LL.D.

Dr. David W. Cheever in his introductory remarks spoke of the growth of the Association, and also of its losses by death. Among these was the name of Francis Minot, long associated with the best interests of medicine in Boston, and for many years a professor at the Harvard Medical School. Dr. Cheever also alluded to what he termed "a burning question, which has been settled against us." He referred to the question of the right of graduates of professional schools to vote for overseers of the University, and was full of confidence that the matter would ultimately be settled in a spirit of liberality. The now definite prospect of a new Medical Library building was naturally a source of congratulation to the entire medical profession.

Following Dr. Cheever's remarks, Dr. Francis H. Brown read the report on the Medical School, which was essentially a narrative of continued progress toward improved methods and results.

In introducing Dr. Wood, the President gracefully laid stress upon his professional rather than upon his military title, speaking of him as "Dr. Wood, physician and sanitarian, rather than as Major-General Wood, military governor of Santiago." In a speech full of simplicity and earnestness Dr. Wood narrated the events of the last few months, with which we are all more or less familiar, but which on this occasion struck a peculiarly responsive note, coming from a man who stands unique in the history of the war as a fearless soldier and a marvellously successful sanitarian. It was gratifying, too, to hear on the following day from one so well qualified to speak on the subject, that the Cuban character has many undeveloped possibilities, if it be rightly directed, and that the future of Cuba has its bright as well as its discouraging aspects. Whatever the value of a pessimistic point of view may be, it is always a relief to hear from men of experience that when the conditions are met face to face, the prospect is, after all, not so depressing. Dr. Wood's remarks throughout, both at the meeting of which we are speaking and at the commencement dinner in Cambridge the following day, bore the stamp of a perfectly healthy, vigorous mind, of a man of action regarding matters of which he had first knowledge.

Dr. Herbert L. Burrell continued the after-dinner speaking by a careful consideration of some of the problems with which medical education has to deal. He spoke of the changes which are being forced upon us, and deprecated the fact that a certain tendency toward neglect of the practical side of medicine was becoming apparent that students, however skilled in the recognition of disease, were often ignorant of the methods fitting them to care for patients. He felt that there is at present a certain gap between so-called scientific and practical medicine, which should, if possible, be bridged. As improvements Dr. Burrell thought the teaching board might be more thoroughly organized; the student brought more in contact with the patient, and the line between required and elective knowledge be more sharply drawn.

Dr. E. H. Bradford reviewed very briefly the work of the hospital ship *Bay State*, with particular reference to the disinterested services of the physicians who made up its staff, and of the others who worked under the auspices of the Massachusetts Volunteer Aid Association. He also referred to Dr. Wood in a way much appreciated by his audience.

It is rare that President Eliot has not some word of hope to give on occasions of medical gatherings. This occasion was certainly no exception. He spoke of the ease with which endowments in medicine may now be secured, owing to the growing confidence of the community in the importance of medical research, and outlined the plan for the foundation of a school of comparative medicine, to which reference has been made editorially in our issue of June 15th. He referred also to the bequest of the late Calvin Ellis in glowing terms, and in his usual happy vein characterized "the medical profession as the true missionary profession of to-day."

The after-dinner speaking was brought to a close by remarks from Dr. Freeman Allen, of the graduating class.

Perhaps never before has the question of medical education and all it involves been in so unsettled, and yet in so encouraging, a state as just at this time. It will require a large measure of judgment and great

resources to attain the best results in the years to come, but we are sure that a free presentation of the difficulties and open discussion will best conduce to this end. This in a degree the annual meeting of the Harvard Medical Alumni Association tends to bring about.

A NOTABLE BEQUEST.

IT has recently been made known that the estate of the late Calvin Ellis has become available for medical purposes. The estate amounts to nearly $400,000 and by the wish of the testator its income is to be devoted to the advancement of the departments of anatomy, physiology and pathology at the Harvard Medical School. Dr. Ellis was at one time Dean of the Harvard Medical School and for many years one of its most distinguished clinical professors. He felt what others have also felt, but been unable to express materially, that teachers of non-clinical subjects do not receive a just reward for their services; the first provision of his bequest therefore was that the professors of the several departments mentioned be paid $5,000 a year, which had already been done, and then the income remaining be made available for the development of the three fundamental branches of medicine, anatomy, physiology and pathology.

Could the benefactor have forseen the exact lines in which medicine was destined to develop, he could not have given more wisely, for the great need of the present, and it will be a constantly increasing need as time goes on, is endowment for the maintenance and growth of laboratories and the cultivation of research, which the existence of such laboratories implies. It is hardly possible that he could have fully realized the enthusiasm for research which was so soon to lead to the development of what we popularly call "scientific medicine," though it had already begun during the latter years of his life. Be that as it may, the bequest is a most notable one, coming as it does from a man who, although himself personally interested in the clinical side of medicine, yet had the breadth of vision to see that the future needs of medical education would require that which money alone can give, in the development of its more theoretic aspects. In President Eliot's words when the announcement was made; "Could pecuniary resources possibly be more timely, and could there be a more delightful benefactor of the advancement of medical science than Calvin Ellis?"

THE MASSACHUSETTS SCHOOL FOR THE FEEBLE-MINDED.

FOR the first time in its history the trustees and members of the corporation of the Massachusetts School for the Feeble-Minded at Waverley received certain invited guests on June 20th, for the purpose of demonstrating the actual workings of this most worthy charity. All those who availed themselves of this opportunity, we are assured, came away with a renewed sense of the extreme interest and significance of the work being done at the institution in caring for the hopelessly deficient, and in training those, fortunately the larger proportion, who have still possibility of mental development.

The visitors, of whom there were possibly one hundred and fifty, were shown through the various buildings by the superintendent, Dr. Walter E. Fernald, who demonstrated the methods used in the treatment and education of the various degrees of mental deficiency. Later a demonstration of class-work was given by the teachers in charge, which was surely a revelation to most of those present.

The institution is one of which the State may well be proud; it has an interest peculiarly its own, and one too little appreciated by the profession at large. We have been hearing much, of late, of education in the broad sense, as one of the therapeutic aids of the enlightened physician, and nowhere may one see the possibilities of systematic physical and mental training reduced, as it were, to their lowest terms, so well exemplified as at such an institution. Few of us are aware of what is being accomplished so near at hand, in the way of carefully worked-out scientific training for these unfortunate outcasts. A visit forces upon one a sense of the constantly widening scope of medicine, and of its possibilities in a field regarded a few years ago as absolutely hopeless.

We sincerely hope, for the good of the people at large, and indirectly for the benefit of the institution, that the hospitable action of the trustees may be repeated each year.

MEDICAL NOTES.

YELLOW FEVER AT PANAMA. — Over forty cases and twenty deaths from yellow fever were reported at Panama during the months of May and June.

THE HELMHOLTZ STATUE. — The statue of Helmholtz, in the court of the University of Berlin, was unveiled on June 6th, in the presence of the German Emperor.

"NEGLECT, DROPSY, AND CHRISTIAN SCIENCE" AS CAUSES OF DEATH. — According to the *Chicago Medical Recorder* for June, a Christian Scientist died a few days ago in Mount Vernon, N. Y., after a three months' illness, during which she persistently refused medical treatment. The coroner endorsed on the death certificate that she died "of neglect, dropsy, and Christian Science treatment."

THE IMPERIAL SCHOOL FOR TROPICAL DISEASES. — We learn from *Science* it has been decided that the Imperial School for the Study of Tropical Diseases, the establishment of which is due to the suggestion of Professor Koch, is to be settled at Hamburg. Professor Koch originally wished to have it in Berlin, but reasons of convenience have led to the substitution of

Hamburg, where patients can be landed directly. The institution is for the present to be equipped to receive thirty patients.

APPOINTMENTS AT JOHNS HOPKINS UNIVERSITY. — Dr. J. Whitridge Williams, associate professor of obstetrics, has been appointed to the full professorship; Dr. L. F. Barker, associate professor of anatomy, has been appointed associate professor of pathology; Dr. R. G. Harrison has been appointed associate professor of anatomy.

TROPICAL MEDICINE AT UNIVERSITY COLLEGE. — Major Ronald Ross, I.M.S., inaugurated his first course of lectures on Tropical Medicine at University College, Liverpool, on June 12th, by an address on the "Possibility of Extirpating Malaria," in which he dealt in detail with the means of exterminating malaria-bearing mosquitoes.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 5, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 70, scarlet fever 21, measles 54, typhoid fever 10.

BOSTON PHYSICIANS HONORED. — Dr. C. S. Minot, Harvard Medical School, has been honored with the degree of LL.D. from Yale University; Dr. W. T. Councilman, Harvard Medical School, has received the honorary degree of A. M. from Harvard University.

BOSTON SOCIETY OF MEDICAL SCIENCES. — The last meeting of the year was held at the Harvard Medical School, June 20, 1899. The following papers and communications were presented: Dr. C. G. Page read a paper on "A Preliminary Study of Streptococci Isolated from Throat Cultures from Patients Ill with Scarlet Fever," and spoke of future work to be done in isolating varieties of streptococci. Dr. Page also demonstrated lantern-slides of a bacterium, possibly the cause of scarlet fever. Dr. Theodore Hough spoke on the effect of temperature on capillary blood pressure in the skin, and concluded that the muscles of veins and arteries work together to maintain a constant pressure. Dr. S. A. Hopkins gave a preliminary report on his experimental work on the relation of bacteria to dental caries. Drs. W. T. Porter and H. G Beyer spoke of cardiac vasoconstrictor fibres in the vagus nerve.

NEW YORK.

OVERWORK IN THE PUBLIC SCHOOLS. — At a meeting of the North Side Board of Trade, held June 27th, at which the necessity for additional school facilities in the Borough of the Bronx and the studies of children in the public schools were discussed, a report from the Committee on Education was presented, in the course of which it was said: "Our attention has been called to what would appear to be almost a physical wreck of some of our highest and best scholars, caused, as we believe, by the great amount of study forced upon them; and we deem it our duty to suggest that the children in our schools should have fewer studies, the result of which, we believe, would be far better than forcing them to such an extent that they cannot sleep from worry. We believe that a more thorough and exhaustive system of gymnastic exercise should be attached to our schools, and made a more prominent feature." The report was unanimously adopted, and among those who spoke in favor of it was Dr. Emil Heuel, a highly esteemed practitioner of the Borough, who cited the case of his little nine-year-old daughter as an example of the result of the cramming system. "She comes from school," he said, "complaining of nervous headache. It is ridiculous for a child of her age to know anything of such an ailment." Dr. Heuel was of the opinion that the mental development of the children was cultivated at the expense of their physical, and that the remedy for this state of affairs was more physical exercise and less brain-work. Apropos of this matter it is stated that the School Commissioners of Brooklyn are contemplating the experiment of a high school for girls which, in addition to mental instruction, shall afford systematic practical training in domestic economy and the industries most practised by young women who have to work for their living. The public school system, it is said, trains girls to be clerks or teachers, stenographers or business women, but gives the other girls, who form a majority, no opportunities to fit them for bread-winning.

A DEATH FROM CHLOROFORM. — A death from chloroform is reported in the practice of Dr. Joseph Muir. The patient was a boy nine years old, suffering from adenoid or other form of growth in the fauces obstructing respiration, and the operation for its removal had not yet been commenced when the fatal result occurred. The chloroform inhalation was conducted by an experienced operator, Dr. George Krauder, house-surgeon of St. Mark's Hospital.

YELLOW FEVER AT QUARANTINE. — A case of yellow fever was brought to quarantine on the steamship *Krim*, of the Munson Line, which arrived from Havana and Matanzas on June 29th. Dr. Doty decided that he would not try his serum on the patient, as the case was very far advanced (seven days) and was already doing very well, with an excellent chance of recovery.

HOW THE COST OF MEDICAL CHARITIES TO THE CITY MIGHT BE LESSENED. — The Controller has come to the conclusion that fully half of the three million dollars, including the amount received from the excise funds, which the city last year appropriated to private charities, can be saved by the Stranahan law, enacted by the last Legislature, which gives the Board of Estimate authority to make only such appropriations as it sees fit, and repeals the mandatory provisions of the charter appropriating specified amounts to a number of institutions. That too liberal appropriations by the city have a tendency to lessen

private contributions is well shown by a series of comparisons of income taken from the late report of the State Board of Charities. From this it appears that while the New York Foundling Hospital last year received $310,417 from the city, it obtained only $6,450 from private sources, the New York Infant Asylum received $86,457 from the city, against $145 from private sources, and the Colored Home and Hospital, $18,967 from the city, against $474 from private sources. Mr. Coler has been in conference with the State Board of Charities with reference to the whole matter, and has now received a letter from the secretary of the Board, Mr. Hebberd, in which he says in part: "It seems to me important and necessary that there should be in connection with your office a well-equipped bureau of charitable institutions, which through the work of inspectors and otherwise should collect, classify and file for ready reference all the useful information it is practicable to obtain with relation to those charities which seek the assistance of the city. It would seem entirely feasible and proper to make a rule to the effect that no money would be given to any charity which neglected or refused to furnish such information respecting its management as your office might require. The result of such a rule should be to let a large amount of hygienic sunlight into some institutions which are charitable when seeking donations, but not even eleemosynary when attempting to evade examination. As a general proposition, it would seem desirable to limit appropriations to charities to an amount commensurate with the useful public services rendered by these institutions, as far as can be determined. It rests entirely within the discretion of the city authorities to say how much money they wish to give to private charities, and also to see that those having the care of inmates expend the money wisely. Beyond this, to well-conducted charitable institutions and societies for beneficent purposes not having the care of inmates, a reasonable apportionment might be made, based somewhat upon the amount of private donations received by such society, and with the direct understanding that the city's moneys were to be used for the actual assistance of the poor, and not for administrative expenses.

THE BROOKLYN MILK SUPPLY. — The president of the Board of Health has requested the sanitary superintendent to make a special investigation of the milk supply of Brooklyn, as he has reason to believe that it is not as pure as it should be. Recent returns, he says, show that the large number of deaths of children, under the age of five years, in the Borough of Brooklyn (68 in Brooklyn, as compared with 33 in the Boroughs of Manhattan and the Bronx), is caused by other than climatic reasons.

THE MOUNT SINAI HOSPITAL. — In the competition of architects for plans for the new Mount Sinai Hospital, the award has been made to the design of Arnold W. Brunner, and excavation has already been commenced for the foundations. The new buildings which, exclusive of the land, are to cost about $800,000, will occupy the greater part of the block between Fifth and Madison Avenues and 100th and 101st Streets.

ARMY NOTES.

LEPROSY IN CUBA AND PORTO RICO. — Energetic measures are being taken to properly segregate all lepers in Cuba and Porto Rico. The San Lazaro Hospital in Havana now contains 370 cases of leprosy, although four months ago there were only eighty inmates. In view of this increase the institution, although well endowed, has found it necessary to ask for an appropriation of several thousands of dollars to properly continue its work. The hospital is in charge of Sisters of Charity.

THE MEDICAL DEPARTMENT PRAISED. — *The Journal of the United Service Institution of India* for April last contains an elaborate report by Capt. S. S. Long, Assistant Adjutant-General in the British Army, on the administration of the United States forces in the Philippines. Captain Long, who spent the winter and early spring in and around Manila, after free criticism of the Quartermaster's, Engineer and Ordnance Departments, speaks in terms of the highest commendation concerning the Medical Department and praises the equipment and administration of the hospitals. "The health of the troops was extraordinary," he says, "and the subject of constant remark. If the spirit of the troops was excellent it was even surpassed by that of the medical branch, who, in spite of inadequate and defective transport facilities and many other difficulties, always had their hospitals as complete and efficient as human ingenuity could make them."

SICK AND WOUNDED RETURNING. — The transport *Morgan City* sailed from Manila on June 24th for San Francisco, having 464 sick and wounded on board.

DEATHS OF TWO SURGEONS. — During the past fortnight two bright young medical men of the army have died from disease contracted in the line of duty in the military service. First Lieut. R. B. Westnedge, Assistant Surgeon, U. S. Army, died in Manila, as a result of typhoid fever. Dr. Westnedge was appointed an assistant surgeon in December last, after having taken an excellent standing in the class before the army medical examining board. He was a graduate of Rush Medical College and had completed a term as interne at the Cook County Hospital. The second death was that of Acting Assistant Surgeon F. W. Fabricus, U. S. Army, who succumbed to yellow fever at Santiago. Dr. Fabricius was a candidate before the army medical examining board at the same time as Dr. Westnedge but was rejected for physical deficiencies. Attracted by a military life he was given a contract and sent to Santiago, where he was made pathologist to the general hospital and had been carrying on earnest investigations on the subject of Cuban mala-

ria. It is supposed that Dr. Fabricius contracted yellow fever during the autopsies performed on the first cases which occurred in the recent outbreak of the disease at Santiago.

Miscellany.

MOVABLE KIDNEY.

L. L. McARTHUR advocates a new method of fastening the movable kidney in its new position: (1) A curved transverse incision below the last rib is made through all the structures at once down to the peritoneum anteriorly; (2) the peritoneum is then loosened from the lateral parietal walls by blunt dissection sufficiently to permit boldly enlarging the posterior angle of the wound without fear of injury to important structures quite back of the quadratus; (3) fatty capsule of the kidney loosened by blunt dissection; (4) the anterior layer of the lumbar fascia and transversalis aponeurosis is then loosened from the tissues on which it lies, to such an extent as will admit the kidney in the pocket thus made, the lower flap of the wound having a compartment for the lower half of the kidney; (5) prior to inserting the kidney in the new compartment, the cut edges of the transversalis aponeurosis have inserted in them two or three stitches, which serve to pucker the pocket containing the kidney; (6) the kidney having been dislocated first upward, its lower end is slid into the pocket; (7) closure now of the stitches in the aponeurosis of the transversalis fixes the lower half of the kidney external to one of the layers of the abdominal parietes, supporting the same by so broad a surface that no injury to kidney can result and no displacement occur, and employing a normal tissue not transplanted. He thinks that a pocket large enough to hold the lower half of the kidney is all that is necessary, but the kidney should be fixed in position by two or three stitches in order to hold it securely until adhesions form. It cannot be dislocated by pressure from above, which now only tends to drive it deeper into the pocket.

URETERO-URETERAL ANASTOMOSIS.

MARKOE and Wood[1] report a case of considerable interest from the point of view of diagnosis and treatment. In the course of a hysterectomy for an intraligamentous fibroid a section of the right ureter an inch and a half long was removed under the impression that it was a vein entering the tumor. The left ureter, though not cut, was so sharply kinked in the closure of the peritoneal flaps that it was completely shut off. Recovery from ether was normal, but anuria ensued, and resulted in an examination of the tumor and the identification of the section of the right ureter. The abdomen was reopened at once and both ureters found distended. The left ureter was freed by loosening the stitches which held it, and there was an immediate discharge of the retained urine into the bladder. On removing the ligature from the proximal end of the divided right ureter urine escaped into the wound. Uretero-ureteral anastomosis was then performed by invaginating the proximal end into the distal end over a catheter, which was brought out through the meatus, and circular suture. The catheter was left *in situ* for five days. Vaginal and abdominal gauze drainage was provided, and the patient made a good recovery.

A point of interest about the case is that the complete obstruction of both ureters resulted in no marked pain, or other violent subjective symptoms, and that the continuance of the obstruction for twenty-four hours did not prevent complete recovery of function.

[1] Annals of Surgery, June, 1899.

THE RANK AND PAY OF THE SURGEON-GENERAL.

THE following resolutions were adopted by the Medical Association of Georgia at its fiftieth annual session at Macon, last April:

Whereas, The position of the Surgeon-General of the United States Army involves great and grave responsibility, the direction of vast interests, the highest order of professional skill and learning and executive ability, and

Whereas, The number of officers and soldiers under the direction of the surgeon-general in an army organized as is the Army of the United States is greater than the command of a division commander,

Be it resolved, By the Medical Association of Georgia, that it is the sense of this body that the Surgeon-General of the Army should have the rank, pay and allowances of a major-general.

Resolved, That the Medical Association of Georgia requests all the medical societies of the United States to join in this appeal.

Resolved, By the Medical Association of Georgia, that copies of these resolutions be transmitted to the President of the United States, the Honorable Secretary of War and our senators and representatives in Congress, with the request that all co-operate in attaining the end sought; and further, that copies be also sent to the American Medical Association, and all other medical societies in the United States, with the request that they join in this memorial to Congress and urge prompt action upon this subject by our national legislative authorities.

METEOROLOGICAL RECORD

For the week ending June 24th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Melrose . . .	14,032	3	—	—	33.33	—	—	—

Deaths reported 2,361; under five years of age 897; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 387, consumption 270, diarrheal diseases 218, acute lung diseases 194, diphtheria and croup 70, whooping-cough 23, typhoid fever 21, scarlet fever 19, measles 15, erysipelas 11, cerebro-spinal meningitis 8, small-pox 2.

From typhoid fever Philadelphia 9, New York 5, Baltimore 2, Boston, Washington, Nashville, Worcester and Everett 1 each. From scarlet fever New York 14, Philadelphia 3, Washington and Worcester 1 each. From measles New York 12, Nashville, Lowell and Waltham 1 each. From erysipelas New York 7, Boston 2, Springfield and Quincy 1 each. From cerebro-spinal meningitis New York 7, Nashville 1. From small-pox New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 11,404,408, for the week ending June 17th, the death-rate was 16.5. Deaths reported 3,607; acute diseases of the respiratory organs (London) 207, measles 142, whooping-cough 91, diphtheria 83, diarrhea 48, scarlet fever 25, fever 25, small-pox (Liverpool and Hull 1 each) 2.

The death-rates ranged from 9.0 in Croydon to 24 8 in Manchester; Birmingham 19.4, Bradford 15.9, Cardiff 9.3, Gateshead 19.6, Hull 16.5, Leeds 16.6, Liverpool 20 6, London 15.1, Newcastle-on-Tyne 15.5, Nottingham 17.4, Portsmouth 15.0, Sheffield 18.2, Swansea 17.1, West Ham 11.8.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 1, 1899.

W. L. BELL, assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., and ordered to the "Philadelphia."

H. E. ODELL, assistant surgeon, detached from the "Philadelphia" and ordered to the Naval Hospital, Mare Island, Cal.

F. M. BOGAN, assistant surgeon, ordered to additional duty at the Boston Navy Yard.

R. G. BRODRICK, passed assistant surgeon, ordered to Washington, D. C., July 6th, for examination for retirement and then home and to wait orders.

J. C. ROSENBLEUTH, passed assistant surgeon, detached from the "Buffalo," when put out of commission, and ordered to the "Vermont" immediately.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JUNE 29, 1899.

SAWTELLE, H. W., surgeon. Detailed as inspector of relief stations of the third and fourth class. June 27, 1899.

WOODWARD, R. M., passed assistant surgeon. Upon being relieved by Passed Assistant Surgeon A. R. THOMAS, to proceed to Washington, D. C., for assignment to duty. June 26, 1899.

THOMAS, A. R., passed assistant surgeon. Upon being relieved by Passed Assistant Surgeon G. T. VAUGHAN, to proceed to Reedy Island Quarantine Station and assume command of the Service. June 26, 1899.

HALLET, E. B., acting assistant surgeon. Granted leave of absence for two days from July 4, 1899. June 27, 1899.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence for three days from June 28, 1899. June 26, 1899.

BRUNNER, W. F., sanitary inspector. Granted leave of absence for three days from June 28, 1899. June 23, 1899.

RODMAN, J. C., sanitary inspector. Granted leave of absence for seven days from June 27, 1899. June 23, 1899.

THURSTON, E. J., hospital steward. To proceed to New York, N. Y., for special temporary duty. June 26, 1899.

PROMOTION.

PETTUS, W. J., passed assistant surgeon. Commissioned as surgeon. June 26, 1899.

APPOINTMENT.

FREDERICK TOWNSEND, of Michigan, to be acting assistant surgeon, for duty at Sault Ste. Marie, Mich. June 23, 1899.

RESIGNATION.

HAROLD C. ERNST, M.D., professor of bacteriology in the Harvard Medical School, has resigned his appointment as physician to out-patients in the Massachusetts General Hospital, the demands of his laboratory calling for all his time.

SOCIETY NOTICE.

AMERICAN OTOLOGICAL SOCIETY. — The thirty-second annual meeting of the Society will be held at the Pequot House, New London, Conn., on Tuesday, July 18, 1899, at 10 A.M.

FREDERICK L. JACK, *Secretary*.

RECENT DEATHS.

BENJAMIN FRANKLIN CLOUGH, M.D., M.M.S.S., of Worcester, died May 8, 1899, aged sixty-one years.

JAMES O'REILLY, M.D., of New York, died on June 26th, of paralysis. He was born in Ireland in 1828, and studied medicine at the Royal College of Physicians and Surgeons, Dublin, and the Medical Department of the University of Vermont. He retired from active practice more than ten years ago.

FRANCIS E. NOBLE, M.D., of Jersey City, died of pneumonia on June 29th. He was born in New York in 1824 and had practised in Jersey City since 1850.

BOOKS AND PAMPHLETS RECEIVED.

Modern Anatomy. By Edmund W. Holmes, A.B., M.D. Reprint. 1899.

Transactions of the Wyoming State Medical Society, May and November, 1898.

Report of a Case of Foxtail Infection. By R. C. Chamberlain, M.D., Rock Springs, Wyo. Reprint.

The Standardization of Drugs and the Forthcoming Revision of the Pharmacopœia. Reprint. 1899.

The Effect of Pressure in the Preservation of Milk. A Preliminary Report. By B. H. Hite, Morgantown, W. Va.

International Clinics, Edited by Judson Daland, M.D. Vol. I, Ninth Series, 1899. Philadelphia: J. B. Lippincott Co. 1899.

Notes on Malaria in Connection with Meteorological Conditions at Sierra Leone. By Major E. M. Wilson, C.M.G., D.S.O. London. 1899.

Gonorrhea in Women. Treatment of Endometritis. Gynecologic Diseases: Some Points in the Diagnosis of the More Common Ones. Tampons and Pessaries in the Treatment of Displacement of the Uterus. By T. J. Watkins, M.D., Chicago. Reprints. 1897-99.

Addresses.

MEDICINE AS A PROFESSION.[1]

BY WALTER B. PLATT, F.R.C.S., BALTIMORE, MD.

We are told that no man undertakes to build a house but who first counts the cost, and surely no man will dedicate himself and all his powers to a lifework without considering his fitness, what it has to offer him, whether he will be able to finish what he begins, and whether he will be able to make it a success.

It is difficult to conceive of a profession which ought to develop the faculties of a right-thinking man more fully than that of medicine. There is an intimate contact with all classes of men, a close view of human strength and of human weakness, of human joy and suffering, of the insufficiency of wealth and the misery of poverty, and of the connection between the sound body and the sound mind, of which we have all heard and never before realized.

We also see the enormous influence of heredity in determining lines of usefulness or worthlessness, and the sure degeneration of good old family stock, unless a little of the plebeian is infused every third or fourth generation.

All these things pass in review before the physician, imprinting the force of their truth upon his convictions. Thus his life is a satisfying one. He seldom accumulates much property, but rather a rich store of experiences, reaching upward and downward as far as human nature extends in either direction.

Among the many inscriptions in the Congressional Library who has not been struck with one of the most beautiful of them all? It embodies the creed of most thoughtful physicians, who despise the millinery of religion and the frauds with which some of her bodies are covered. We mean the verse from the Prophet Micah, "and what doth the Lord require of thee but to do justly, and to love mercy, and to walk humbly with thy God?"

Your life will be mostly in the shadow, for who sends for a physician when he is whole in body and mind, is free from pain and full of his accustomed energy, "rejoicing as a strong man"? All the more reason for an abundant supply of genuine good spirits of your own. This is the fruit of a good conscience, a first-rate digestion, and a liking for your kind as you find them, whether straight, crooked or striped. You will soon build up a clear philosophy of life, because you more than other men will see what life really is, what it amounts to and what can be made of it. You will see the beginning and the ending of life, the first and the last breath drawn and know much of what has gone on between these two breaths. You will witness some tragedy, a good deal of comedy, and a little melodrama now and then, with a liberal allowance of cheap acting that can hardly deceive any one.

A physician sees with peculiar satisfaction the mighty motto written over the portals of your university, "Veritas vos liberabit." You will find the truth no *ignis fatuus*, and while you only reach after, and still never reach it, you will not be lead into false paths, nor left standing in the mire.

As a physician you will change many of the ideas you have previously held to be true. One of these is the view you have held of your fellow-men. Men will be found to be much worse than you ever dreamed and much better than you ever supposed; stronger in right purpose than you believed, and failing those nearest them at the critical moment. You will more than accomplish the desire of Adam and become as a god, knowing good from evil more than other men. You will see the human heart stark naked, and beautiful or hideous, as it is made. No robe or cassock can hide the dreadful deformity which you alone of human beings will sometimes see beneath it. No station or high office of great estate will afford the least protection or shelter from your gaze. You will find hearts as dry of human kindness as any rock smitten by Moses in the wilderness was of water, but others brimming over with a constant and endearing sympathy that makes you instant captive. Your ideas of what men usually call the power of religion will be rudely shaken, for you will see men for years devoted to the observance of the churches tremble at the far-off bugle call of the gray angel, while gigantic rascals hear the near rustle of his wings without a tremor. Courage, then, is born and bred in men and we do not shame them for the lack of what God never gave.

Eminent physicians and surgeons are seldom ardent devotees of churches, but I believe no men are more devout in the depths of their being. What man who has an eye to see or a brain to perceive can dissect an eye or a brain, or see a living, thinking man develop from a minute cell, and doubt that an immeasurably wise intelligence devised it? You will believe in the goodness of God from a thousand proofs of it, while the mystery of pain and the misery of poverty as you see it will thrust daily darts into your soul; and, again, in the families you visit, you will see heavenly visions of unselfishness in many mothers and fathers and in some children. You will believe as much in the perfect virtue of many good women as in the almost total depravity of others. At times you will think that all men are liars, until you find those whose perfect truthfulness a thousand times outweighs those dark and devious ways. To know how good and how bad men and women are, you must practise medicine.

I would have every man about to practise medicine spend from three to six months in training in business methods, for, unfortunately, there is a business side to your profession. A physician, eminent for his learning and success, said to me, recently, "Really, the only qualities necessary to practise medicine successfully are politeness and punctuality," which I think I might interpret as tact and attention. Do not look for much leisure, for you cannot have it; do not expect too much gratitude, for that will be an accident dependent upon your personality and not upon your services. Do not think you can be your own master, for you will wash the feet of the poor. Do not think you will live to be old, for most of you will die of Bright's disease before you are seventy. But if you half deserve the name of physician, you will lead a satisfying life, become a reverent philosopher, and, when the end approaches, go,

> "As one who wraps the drapery of his couch about him,
> And lays him down to pleasant dreams."

Who will say that this work is not more than interesting? It is fascinating. It will hold you day and night. You are not a passive spectator, for you control the whole show.

[1] An address delivered to the candidates for graduation of the Johns Hopkins University, May 9, 1899.

To feel that you hold the life of a man in the hollow of your hand, that his earthly career is at the ends of your fingers, that you are surely going to save him from death by your action, by your intelligence, and that his years will go on as if nothing had dragged him to the edge of a precipice and almost over; is not this a triumph greater than that of a soldier, who has taken instead of saved human life? Can you imagine any greater satisfaction than to do this, not once only but many times, not to speak of the pleasure of relieving pain or bringing peace and comfort where there was unhappiness and discomfort.

Every physician should have in his office, for his own edification, the finest obtainable copies of the "Prodigal Son," to see if art can equal what he daily sees and hears. Have a statue of Venus in an opposite corner from one of Cupid, for you are a daily witness of the trouble which comes to young men and old who follow strange gods.

Moreover you must consider whether you love that profession enough to count as nothing a thousand discomforts and risks inseparable from it. Do not forget that there are 106,000 physicians already in the United States, and 165 medical colleges, to see that the supply does not give out. Some of you *must* be physicians or surgeons; you could be nothing else and nothing less. No one would ask a young eagle if he expected to fly, or a fish if he intended to swim. I do not ask these inevitables, "Will you," or, "Will you not," but even you may inquire with me what is the best way to study and practise medicine, whether it is best for me and the rest of mankind that I should undertake to relieve, to cure, to bind up the wounds of the body and heal the broken-hearted, and you will find the wounds of the heart and the pains of the soul hardly less common and demanding scarcely less tact and patience than those of the bone and flesh. Whether you will be physicians or surgeons or specialists need not now concern any of you, but whether you will be a physician at all.

No profession more strongly marks men than that of medicine. Make up your mind to that, and that whatever be your individuality it will be second and your profession first, if you are worthy of it. You will have certain characteristics of a class. You will not live as long as if you were a clergyman. The irregular hours, the sedentary life, the wear and tear of competition and of the weight of others' woes will take off a few years. What of that! We do not reckon our lives in that way! While fewer physicians become insane than members of many other occupations, a larger proportion become addicted to the use of morphine, and one of your first vows should be never to take that drug without the advice and supervision of a brother physician.

You will be somewhat more liable than other men to contract tuberculosis if you are much in contact with it in your hospital and laboratory work. You will be considerably more likely to take scarlet fever than other mortals. If you do any surgery, you will run some danger, and that not a little, of infecting yourself with septicemia. No one would surely draw back because of these! A well-known physician said to me that he thought nearly every physician had nervous exhaustion. I hardly believe this true to the extent he intended, but many of them do have something very akin to this.

Medicine is only one and the noblest of the so-called natural sciences, and rests upon the firm base of morphology, biology and chemistry — a splendid trinity. As with the early Christians who had divers gifts, some to be apostles, some evangelists and some teachers, so will medical men work in many fields. Some will take naturally to medical journalism, others to the laboratory, some to hospital work, while most of them will practise medicine in one or another department. About one-tenth of all who graduate in medicine give it up. With good preparation, fair health, plenty of industry and no end of earnestness, with a certain amount of tact and talent, your success is one of the surest things in life.

Do not suppose you can enter at once upon a practice. Two years elapsed before his first patient entered the office of one of the best-known physicians in New York City. I know of another who faithfully waited in his office on Madison Avenue one year without having a single patient. I well remember my first patient, who chanced to be a Johns Hopkins student and in great fear of baldness although blessed with hair of great length and luxuriance.

If you have any sense of humor and a proper amount of self-control, your medical experience will be as entertaining as instructive.

Do not hesitate to study medicine merely because you feel faint at the sight of sickness or wounds. I well remember seeing a friend, now one of the most eminent physicians in New York City, turn the color of sage-cheese and make a bolt for fresh air when he had the study of medicine in mind and had gone to the hospital to witness some simple, bloodless surgical procedure. At the opening of each year at the Harvard Medical School two men are stationed at the door of the amphitheatre to carry out the new students who fall fainting. This signifies no more than the peculiar and disagreeable sensation good soldiers usually have when first under fire.

As a boy every one of you has doubtless twirled a magnet round and round over a compass and watched the needle beneath, follow its every turn. If that needle were wood or lead, there would be no such eager following. If you are made of the right metal you cannot but follow where your profession leads, and you must feel toward her as a man feels toward the love of his heart; he must have that particular woman and none other. Like Cleanthes in his hymn to Zeus, "Still must you follow on" if you are true to medicine.

If you are destined to enter our profession, you will find well-written sketches of eminent medical men delightful reading. See what kind of a man was Johannes Müller, Jenner, Pasteur, or our own Austin Flint, Benjamin Rush or Henry J. Bigelow. Read of Lister and Koch, of Virchow, Langenbeck and Billroth, and if the cockles of your heart do not glow, you can never take fire from our shrine. Get some hospital house surgeon to take you on his visits, look at, listen to and feel what he shows you in hospital wards, and if you can be dragged away without the keenest regret that you may not stay longer, you are not worthy. Do not think for a moment that any amount of brilliancy or influence will avail in the long run. One thing only gives solid reputation, and that is a great deal of good work. It has been my good fortune to meet and know some great medical men, and not one of them but won his laurels by continuous hard work.

One of the characteristics of all virile men is the

wish to make every man with whom they come in contact feel and think as they do. They are secular missionaries. You must make up your mind to be missionaries of hygiene for the rest of your lives. But most men will still do as they choose, preferring the possibility of a cure to a certain prevention.

You will be in very good company. Jenner, Pasteur, Roux and Koch, Behring, McDowell and Morton will lead. What other man than Edward Jenner since the world began has saved directly, by one single discovery and invention, several millions of lives? and could a monument as high as Heaven itself be too high for such a man! Think of the laurel crown for the man who discovers a cure for consumption and for cancer! You will surely never lack for lofty aims if you study medicine. Think of that horrible and heretofore absolutely hopeless disease, hydrophobia, and of its reasonably certain cure by a few harmless and painless injections, the discovery of Pasteur. Think of the scourge diphtheria was, and the comparatively innocent disease it has become when treated with early intelligence according to the method of Behring and Roux. All our recent and great cures have been thought out by men of the laboratory, who could look through microscopes and know what they saw, who could sacrifice a few animals on the altar of science that men might live. Great universities like this, your Alma Mater, provided these laboratories and gave their devotees food while they worked.

Sir James Paget, in an address before the Medical School at Leeds (1865), says: "I suppose that one of the keenest of intellectual pleasures is in the clearing of a view of truth." Now, your whole professional life will be filled with that pleasure or may be so filled.

Dr. Da Costa puts it well when he says (Valedictory Address, 1883): "To be the welcome visitor, the one to whom all turn in trouble, and to whom family secrets are confided with the freest faith that they will be sacredly guarded; to be eagerly sought for in hours of danger and of anguish and feel that you have the power of relieving; to be the hope of many and the friend of all — this, surely, makes a splendid calling"

We have the authority of Dr. John Draper for the statement that in the early years of European medicine, about the year 1200, nearly every physician of that time was a Jew, and that of the libraries of the universities of Salerno and Montpelier, the two seats of medical learning of that day, one-half the books were Hebrew and the other half Arabic. In a word, European medicine at the outset was Asiatic. In one of those wild waves of antisemiticism in 1306 all Jews were prohibited from practising medicine in France. There is no doubt that the physicians of these times were a weird lot, partly astrologers; later, leeches and barber-surgeons were added to the list, and a little later they were often monks.

The bond of the clergy is honored to this day by most physicians, in making no charge for their services, although we never knew our clerical brethren decline a marriage fee when it was pressed upon them. Medicine once sought the cloister; it now seeks the laboratory. More than ever it is a matter of physics, and disease something to be seen, heard or felt in one way or another. You need first a habit of trained, careful observation, and next a logical mind, for without a correct interpretation of symptoms, you are but a droning chronicler and not the trained historian of your patient's case. The perfection of science is prophecy, and given certain conditions you can now tell your patient what is to come. Unlike the astronomer, we cannot foretell the hour and minute, but we approach ever nearer to that ideal.

The splendid professional and social standing of Boston physicians is well known, and clearly due first to their training in a great university, and then to an enlightened public opinion. In a delightful address before the students of the Harvard Medical School (1870), Professor Andrew Peabody said: "The physician should be a gentleman. By a gentleman I mean not a person who in certain circles conforms to the conventional canons of good breeding, but one whose genuine kindness of heart never fails of its due expression in courteous speech and manners on all occasions and toward all descriptions of persons."

Boards of foreign missions have only lately learned that the missionary must be either a doctor or else he must have one in close relationship with his work if the heathen are to take any stock in his labors. One of the most important of the white man's burdens is to bind up the wounds and heal the diseases of his black, brown or yellow brother. As a physician I believe it would do more to pacify and reconcile the Filipinos to our rule to build a hospital and a school-house in every town than many soldiers and many promises of good things to come.

Physicians succeed in many things besides medicine. As you are all aware, many of our foremost men of science, especially in the fields of botany, zoölogy and biology, have been physicians. Witness Huxley, the elder Darwin and a hundred others. Among great travellers we see Mungo Park and Livingstone. The names of Oliver Wendell Holmes and Sir Thomas Browne will instantly occur to most of you as examples of the physician in literature. I believe they are poor politicians and never statesmen. A physician has never been President, seldom governor of a State, and rarely even a mayor of a large city. They have often been noted soldiers, and take kindly to war and rumors of war. The late Mr. Justice Miller of the United States Supreme Court told me that he practised medicine for five years, and if he could have had a surgical practice, he would have never studied law, but medicine as then known was too uncertain, too illogical to satisfy his mind. With him surgery was the one thing needful. We lost a good surgeon, doubtless, and gained one of our best judges. Senator Gallinger of New Hampshire, albeit a homeopath, is an M.D. Count Rumford studied, although he never practised, medicine.

Physicians are often able administrators, and make excellent superintendents of institutions. We know the laurels Dr. and Col. Wood has won as military governor of Santiago. It may be gratifying to some of you to learn that many of the most successful physicians did not stand at the head of their classes in college, while it is a singular fact that many surgeons were very dull even in the study of medicine, and seemed to gather a strange force and purpose after passing their year in a hospital.

A physician ought to be a gentle Stoic, a bit of an Epicurean, and a true Christian gentleman. We read that Arthur, when he made a knight, said: "Be ye a good knight, and so I pray to God, so ye may be, and if ye be of prowess and of worthiness, ye shall be a knight of the Table Round"; and we who are physicians say this to every one of you.

THE CAVENDISH LECTURE ON THE ETIOLOGY AND DIAGNOSIS OF CEREBRO-SPINAL FEVER.[1]

BY WILLIAM OSLER, M.D.,
Professor of Medicine, Johns Hopkins University, Baltimore, Md.

(Concluded from No. 1, p. 6.)

III. *Lumbar Puncture.* — During the past ten years no single measure of greater value in diagnosis has been introduced than Quincke's lumbar puncture. We are now able in a large number of cases to make a prompt decision as to the existence of meningitis, and are further enabled to recognize the form of the disease. I shall not detain you with details of the technic, available in all text-books, and recently considered at great length in an elaborate "Referat," by Neurath, in the *Centralblatt f. d. Grenzgebiete der Medizin und Chirurgie*, Bd. I. It is a simple, quite harmless procedure, and in a majority of the cases can be done without general anesthesia, or with the aid of a local freezing mixture. A dry tap is rare in cerebro-spinal fever; the needle may be plugged with fibrin, or a nerve root may come directly against the orifice. Puncture in the third or fourth interspace may be negative, while in the second a free flow is secured. In one of our early cases in which no fluid was obtained the autopsy showed an exudate as thick as butter, with little or no fluid. A first puncture in a case is very often negative. Though simple, the technic is, like other procedures of the kind, bettered by practice. Very often at first a few drops of blood flow, then a clear or turbid fluid, either drop by drop, or sometimes in quite a strong stream.

The fluid may be clear, turbid, purulent, or more rarely a brownish yellow, or quite bloody. In a great majority of all cases when meningitis is present the fluid is turbid. In rare instances clear fluid may be obtained when meningitis exists, and in a protracted case the fluid may be turbid at one puncture and clear at the next. Several observers have noted that the fluid may become clear in the intermissions of the disease. A clear fluid may be obtained from a puncture in the second lumbar interspace, while lower down a turbid fluid may be withdrawn. I saw this possibility very well illustrated in a recent post-mortem; the fluid in the lower dorsal and upper lumbar regions was perfectly clear, while that in the lower lumbar and the sacral regions of the canal was very turbid and contained numerous flocculent masses.

The fluid should be allowed to flow into a sterilized test-tube. When the fluid is at all turbid there is usually a slight sediment and a coagulation of fibrin. Cover-glass preparations are made either directly from the turbid fluid, or if the turbidity is slight and the cell elements few in number, after it has been centrifugalized. Cultures should be prepared at the time of making the lumbar puncture by allowing one or two cubic centimetres of the fluid to flow on to a Löffler blood-serum medium.

The amount of fluid obtained varies from a few drops to 130 c. c. The samples in these flasks show the large amount which may be removed, one 126 c. c., another 112 c. c.

Wentworth claims that within certain limits there is some relation between the degree of turbidity of the fluid and the severity of the symptoms, and this was borne out by our more limited experience. Even in the most protracted cases the turbidity may persist. Only once was a clear fluid removed in an exacerbation. On several occasions a bloody fluid was removed in Case 18. In the wards at the same time was a remarkable instance of septic meningitis in which, after turbid fluid had been withdrawn at one puncture, at a subsequent one, before death, blood flowed from the needle, and post mortem there was extensive meningitis and a rupture of the basilar artery with hemorrhages.

The number of the organisms found bears no constant relation to the intensity of the symptoms. In acute cases they are present, as a rule, in large numbers. The later the disease, the less likelihood is there to find the diplococcus intracellularis in the fluid; but we have found them in the second, third, fourth, fifth and seventh week. The following are some of the days on which the organisms were found: 17th day, 14th day, 25th day, 31st day, 41st day and 19th day.

Has the lumbar puncture any therapeutic value? Williams, of Boston, states that he has seen beneficial effects, and there are a few cases in the literature in which the severity of the symptoms were promptly mitigated by the removal of a variable amount of the spinal fluid. Wentworth (whose experience has been very large), speaking of these cases, says: "I have never seen any such cases, though constantly on the watch for them. A temporary relief, lasting for a few hours, has followed the operation in a few cases, but the same remissions frequently occur without any treatment." Netter says that he has seen convulsions, which had lasted for a long time without intermission, cease after the withdrawal of only about two drachms of fluid.

We have given this point our closest attention, and many times have performed the puncture directly for its supposed benefit. In Case 8 the note reads: "Much better after the first puncture; brighter every way." Case 9, puncture at 11 A. M.: "Patient's condition has greatly improved; the muttering has ceased, and the irregular movements are less marked." To Case 16 I may refer more fully. It was an example of the chronic form, in which the patient lingered for nearly three months. The accompanying table has been prepared by Dr. Marshall, one of my house physicians.

It gives the day of the disease, the amount of fluid withdrawn, the character of the exudate, the microscopical appearances, the culture results, the leucocytosis and the effect (?) of the puncture on the temperature. The first puncture, made on the 29th day of the illness, was negative. From the second puncture 100 c. c. of a yellowish turbid fluid was withdrawn, which contained pus cells and intracellular cocci in abundance and the cultures were positive. In all 17 punctures were made between the 29th and the 75th day of the disease, of which 14 were positive. A turbid pale-yellow fluid was removed at each tapping. On five occasions 100 c. c. or more were obtained, once 125 c. c. and once 126 c. c. Following the first two effective tappings the patient appeared better, the temperature dropped and he seemed much brighter, but he soon became worse, and the fever rose. Following the sixth, seventh, eighth and eleventh punctures the temperature fell, 4.5°, 3.8°, 4.2° and 5.8°. There was no change in the general condition, though he sometimes was a little brighter, and the drop in fever followed so directly that it seemed only natural to attribute the

[1] Read before the West London Medico-Chirurgical Society, June 16, 1899. — From advance sheets courteously furnished by the editor of the West London Medical Journal.

good results to the lumbar puncture. The thirteenth puncture, however, was negative, yet the temperature fell 5.1°, and after the fourteenth tapping the temperature rose 2.6°. Evidently not the withdrawal of the fluid, but the peculiar character of the disease, already spoken of, was responsible for the remissions. The chart illustrates further the persistence of the leucocytosis and the sterile characters of the fluid after the 44th day. I have here for demonstration the lumbar portion of the cord and its membranes. The position of the last puncture can be seen and the repeated operations have caused a slight hemorrhagic pachymeningitis.

IV. SPORADIC CEREBRO-SPINAL FEVER.

To what extent do isolated cases of cerebro-spinal fever occur in the intervals between the epidemic prevalence? What is the nature of the primary suppurative meningitis which is met with from time to time in all communities? Neither hospital statistics nor the ordinary death returns give trustworthy answers to these questions. The diagnosis of meningitis is often doubtful, and it is very probable that a great many cases are returned as cerebro-spinal meningitis which are the cerebral forms of typhoid fever or of pneumonia. It is surprising how much confusion there is in the diagnosis of the different forms, and the urgent need of a more accurate recognition of the varieties is well shown by the number of terms used in the tabulation of cases. Thus, not to speak of the tuberculous form, which is often spoken of as basilar meningitis, the terms most frequently used are acute meningitis, meningitis simplex, purulent meningitis and septic meningitis. In a recently issued report on sporadic cerebro-spinal meningitis from the Philadelphia Hospital, by L. N. Boston,[10] exclusive of the tuberculous variety, the following names occur as designating the varieties of acute meningitis; lepto meningitis, basilar meningitis, pachy and basilar meningitis, basilar and lepto meningitis, hemorrhagic meningitis and purulent meningitis.

To reach uniformity in this matter is not at present possible, but we may welcome the steps which have been taken towards separating the different forms of the disease.

In the last Census Report of the United States, the returns for the census year 1890, a year in which cerebro-spinal fever, so far as I know, did not prevail to any extent in epidemic form, the number of deaths reported from cerebro-spinal meningitis was 3,333, a large percentage of these during the first year of life.

From the Fifty-ninth Annual Report of the Registrar-General, 1896, I gather that the deaths from cerebro-spinal fever in England from 1877 to 1896 (inclusive) have only once exceeded 50 per annum. There has been a great reduction in the return since 1887, 233 cases for the ten years ending 1896, against 406 for the previous decade. In Scotland there were only six deaths from cerebro-spinal fever in 1895, and five in 1896. In Ireland there were 76 deaths from this cause in 1896, and the same number in 1897.

From the records of two large metropolitan hospitals I have gleaned the following figures: At St. Bartholomew's, from 1860, cases with the diagnosis of cerebro-spinal meningitis occur in the years 1872, 1888, 1889, 1890, 1892, 1893, 1895, 1896, 1897 — 21 in all. In many years the word meningitis alone is used, in others the word spinal meningitis and meningitis simplex. Ormerod[11] gives an exceedingly interesting report on ten fatal cases from this hospital. Four of them occurred between March and June, 1890, at which time epidemic meningitis prevailed in the eastern counties. At St. Thomas's, since 1873, cases with the diagnosis of cerebro-spinal meningitis occur in the years 1895 and 1896 — seven cases in all. In the wards of the Royal Infirmary, Edinburgh, there were in 1891 three cases diagnosed as cerebro-spinal meningitis, in 1892 two cases, in 1893 one case.

In the United States and Canada the occurrence of sporadic cases of cerebro-spinal fever in the intervals between epidemics has long been recognized. In Montreal I performed post-mortem on at least three cases of acute purulent cerebro-spinal meningitis not associated with pneumonia or endocarditis, and not following otitis media or injury. As illustrating the liability to error, I may mention a case in which the diagnosis of cerebro-spinal meningitis was made in malignant smallpox; in another instance, with the same diagnosis, the case was a very acute typhoid fever, fatal within a week. In Philadelphia I saw only three cases.

At the Boston City Hospital, from 1880 to 1896, there were 39 cases diagnosed as cerebro-spinal meningitis with a mortality of 59 per cent. It is interesting to note that during the first five months of 1897, when the epidemic began, there were 42 admissions, a larger number than in the previous seventeen years. That the disease lingers in a city indefinitely after an outbreak has been the common opinion of all students

[11] Lancet, 1895, No. 1.

of the disease, and any one who has had a large post-mortem experience has met with sporadic instances of extensive suppurative meningitis, which he has not been able to regard as secondary to any existing condition. The Philadelphia records are interesting in this respect. As collected by Still from 1863, the figures illustrate very well the periods in which there were slight outbreaks, namely, 1864–65, and 1872–73. Pepper [12] completed the figures to 1892, and Dr. Abbott has sent me the figures up to date. They show from 1884 a progressive decline in the number of cases, which may in part have been due to more careful diagnosis. From this year, when there were 124 deaths, there was a gradual decline, and in 1891 there were only 23 deaths. From that year the figures, as sent me by Dr. Abbott, are as follow: 1892, 22 cases; 1893, 35 cases; 1894, 18 cases; 1895, 17 cases; 1896, 7 cases; 1897, 10 cases; 1898, 24 cases; 1899 (to and including April 31), 89 cases. Here, again, it is interesting to see how quickly the epidemic prevalence of the disease is manifest. During 1898 the disease was not recognized as prevalent in Philadelphia. During the present year a number of cases have occurred, and the deaths during the first four months have been 89.

In Baltimore, the figures for the past six years are as follow: 1893, 59 cases; 1894, 26 cases; 1895, 27 cases; 1896, 32 cases; 1897, 22 cases; 1898, 70 cases; during this year, the prevalence of the disease was recognized as occurring in a mild form through the city. During the first four months of the present year there has been an increase, and the deaths for this period have been 27.

Sporadic Cerebro-spinal Fever at the Johns Hopkins Hospital.— In the spring of 1898, the first cases of the epidemic form were admitted to hospital, and in all 18 cases have been under treatment. Prior to this date, only four cases had been admitted, which we regarded as sporadic forms of cerebro-spinal fever, three within a few days of each other, in 1893, and one, a chronic case, in 1892, which has been reported.[13]

CASE I. Patrick R. (Hospital No. 7,233), age fifty-seven, admitted May 1, 1893. The patient had been drinking heavily, and when admitted was delirious, mumbling and muttering to himself, and picking at the bedclothes, and he resisted actively any attempt to examine him. His friends stated that he had been in this condition for about a week. His temperature on admission was 97.5°, pulse 68, respirations 16. He had no skin-rash and no symptoms suggestive of meningitis, and we regarded the case as one of delirium tremens. As shown in the annexed chart (Chart VIII), he had no fever until the 5th, four days after his admission. There was then a rapid rise to 105°; the respirations increased from 28 to 40; the pulse rose to 112. Throughout the 6th the temperature remained high, falling on the morning of the 7th to 103°. The respirations rose to 48. He was a little cyanosed, could not be roused, and he died at 8 A. M. on the 7th.

The autopsy (No. 413), showed extensive yellowish purulent exudate over the hemispheres. There was a turbid exudate at the base and along the Sylvan fissures; the ventricles contained an excess of cloudy fluid. The cord was not examined. Cover-slips showed rounded cocci in pairs, chiefly in the mono- and poly-nuclear cells. Cultures showed diplobacilli. The lungs showed slight broncho-pneumonia and the pneumococcus was isolated.

CASE II. Wm. F., age twenty-seven (Hospital No. 7,282), admitted May 3, 1893. The patient was apparently very deaf, and was noisy and delirious when admitted, and he had no friends from whom any history could be obtained. The temperature on admission was 99°, pulse 86, respiration 20. During the night he became very noisy and delirious, and the pulse was irregular. On the following morning examination of the thoracic and abdominal organs showed nothing of any special moment. The spleen was not palpable. The temperature was 99°, pulse 96, respirations 24. On the evening of the 4th and throughout the night the patient became very noisy and had to be transferred to the isolating ward. It was noticed on admission that he was very deaf, and this seemed to increase. On the afternoon of the 4th temperature began to rise, and at 6 P. M. reached 102.5°. The pupils were equal; the pulse was 96, irregular. The patient resisted strongly any attempt to bend the head, and the neck was held very rigid. There was general hyperesthesia, and he cried out whenever he was touched. A petechial rash was noticed this afternoon for the first time over the abdomen. At 8 P. M. the temperature rose to 103°. He became very much worse; the pulse became more rapid, 112, very irregular, and he died a little after two in the morning.

Autopsy (No. 412): A purulent grayish-yellow exudate over the hemispheres, also along the pons and medulla, and the whole length of the spinal cord, which in the lumbar region reached a thickness of 8 millimetres. The ventricles were distended with a turbid yellowish fluid. In the posterior cornua there was a greenish exudate. Cover-slips from the meninges showed numerous leucocytes and large cells containing round diplococci. Pus from the ventricles showed many cocci, single and in pairs, chiefly in cells. Some of the larger cells were packed with these cocci. Cultures were negative. Inoculations of a rabbit and a mouse were also negative. At that time we had not recognized the diplococcus intracellularis of Weichselbaum, but the description of the organism, the position in such numbers within the cells, the failure to grow in cultures, and the negative results of experiments on animals, make it more than probable that we were dealing with this organism.

When these cases occurred the disease was not prevailing in Baltimore, and, except in New York, it was not epidemic anywhere in the country, so far as we could ascertain. Three days after the death of Case I a lad was admitted with a most remarkable family history of the disease. The father, a very intelligent man, gave the following details of the cases:

Wagner Family.— (1) A son, a young man of about twenty years, returned home on Monday, February 7th, complaining of a terrible pain in his head. He had fever with much vomiting, and his head and neck were arched. He was very delirious, became rapidly worse, and died on Saturday, the 12th; (2) a sister who had helped to nurse her brother was taken ill on Monday, the 15th, with similar symptoms, and died in four days; (3) a second sister became affected in a few days and for two weeks was desperately ill; she then began to improve and is now well; (4) the mother, who was worn out nursing the children, was taken ill on March 17th and died in two days. She had slept in the same bed with No. 5, who was admitted to the hospital.

CASE III. W. W., age fifteen, No. 5 of the Wagner family, was admitted May 12th, in the eighth week, of an illness which the doctor described as cerebro-spinal meningitis, and of which his mother and a brother and sister had died. The patient presented a dull, heavy appearance, and for some days did not appreciate his surroundings and appeared confused. He had delusions and hallucinations, and thought he saw his mother and sister in the room with him. He had no fever, and there was no rigidity of the head or neck. The optic nerves looked normal. He improved gradually and was discharged well June 10th.

[12] American Text-book of Medicine, vol. I, p. 163.
[13] Johns Hopkins Hospital Bulletin, 1892.

I can find no parallel to this record in the history of sporadic cerebro-spinal fever. The figures which I have given for Baltimore show that in the year 1893 a considerably larger number of cases occurred than in the four succeeding years, and the admission of these three cases in rapid succession excited our interest, but from this time until the spring of 1898 we saw nothing further of the disease. In the history of the epidemic form it is not very uncommon to find two or three cases from one house. Netter refers to Sewall's report of six children attacked in one family at the beginning of the New York epidemic in 1872, and he quotes from Thorne the statement of Morcieca that in Malta seven cases occurred in a family of nine persons. Such facts speak strongly for the contagious nature of the disease. Under ordinary circumstances, however, it is exceedingly rare to find more than one case in a family, either in the sporadic or epidemic form, and I know of no case in our recent American experience in which a physician or nurse has been attacked, or in which cases have developed among other patients in a hospital. We know nothing of the conditions under which the disease assumes this family malignancy, as it may be termed. In this respect it resembles pneumonia, not highly contagious as a rule, but which may at times, in a family or institution, present a high degree of malignancy.

Bacteriology of Sporadic Cerebro-spinal Fever.— In a number of cases of sporadic cerebro-spinal meningitis the Weichselbaum organism has been found. The case reported by Stewart and Martin [14] is of peculiar interest, inasmuch as the epidemic form of the disease has not prevailed in Montreal for many years. It is to be noted, however, that the patient prior to her illness had been spending a few weeks in Boston, where the disease had been prevailing. An unusual point in this case was the occurrence of an acute purulent pericarditis in addition to the usual cerebro-spinal lesions. The cultures showed the diplococcus intracellularis.

By far the most suggestive contribution to this question made of late years is by Dr. George F. Still,[15] of the Great Ormond Street Hospital for Sick Children. In a study of the form of meningitis known as the simple posterior-basic of infants, he isolated from seven or eight cases a diplococcus intracellularis. The frequency of this form of meningitis may be gathered from the fact that in ten years there were at this hospital 49 fatal cases, verified by autopsy. The smallest number in any one year was two, and the largest number seven. All of these cases were sporadic; none of them formed a part of any outbreak which could be considered epidemic. Clinically the disease presents certain differences from the ordinary type of cerebro-spinal fever, attacking young children, chiefly in the first year of life, and as a rule, is very much more chronic, though there are forms of cerebro-spinal fever which are quite as protracted. Skin rashes are rare, particularly herpes. The most interesting point of similarity determined by Still is the periarthritic affections in certain of the cases of posterior meningitis, involving, as in epidemic form, the capsule of the joint, and the sheaths of the tendons. He determined also in one case the presence of the diplococcus in exudate.

The problem is one which deserves the closest attention, and in every case of sporadic meningitis a careful bacteriological examination should be made for the meningococcus and the pneumococcus, as we are still ignorant of the proportion of cases due severally to these organisms. Two points remain for discussion, namely, the incidence of acute non-tuberculous meningitis in hospital work, and the clinical varieties of the pneumococcic form.

Through the kind permission of my colleague, Professor Welsh, one of his assistants, Dr. W. G. MacCullum, has analyzed from the pathological department of the hospital the cases of meningitis in which bacteriological examinations have been made.

The 25 cases may be divided into four groups:

(*a*) *Cerebro-spinal Fever.* — Six cases (Nos. 412 413, 1,104, 1,189, 1,314, and 1,362).

(*b*) *Pneumococcic Meningitis.* — Eight cases (Nos. 384, 478, 619, 746, 989, 1,082, 1,151, and 1,362).

(*c*) *Pyogenic Meningitis*, in which streptococci or staphylococci, singly or in association, were found — seven cases (Nos. 694, 1,065, 1,092, 1,247, 1,166, 1,363, and 1,364).

(*d*) *Miscellaneous.*— Four cases, two of which (Nos. 854 and 1,091) showed peculiar unidentified bacilli.

The pyogenic forms of meningitis do not concern us here; no case of primary streptococcus or staphylococcus meningitis came to autopsy. I have already referred to the chronic forms of cerebro-spinal fever in which the pyogenic cocci may alone be present at the time of death.

The meningitis with which the diplococcus lanceolatus is associated, in many respects the most important variety, deserves a separate consideration.

PNEUMOCOCCIC MENINGITIS.

As the pneumococcus has long been recognized as the most important organism in the production of meningitis, the first question to be considered is how far sporadic cases of cerebro-spinal meningitis are due to it. Of the 25 cases of meningitis in the pathological department of the Johns Hopkins Hospital, in 8 the pneumococcus was isolated from the exudate. Bacteriological statistics everywhere show the great importance of this organism as a factor in the causation of meningitis. Of 20 cases examined by Councilman, Mallory and Wright, there were 10 cases in which the pneumococcus was found, 8 of these secondary to other conditions, in 2 only primary. In 8 cases of secondary meningitis the streptococcus was present. Netter's experience is particularly interesting. To April, 1897, he had examined bacteriologically 61 cases of meningitis, with the following results: "Pneumococcus in pure culture 35 times, the same associated with the streptococcus and with the staphylococcus each 1 time, the streptococcus alone 13 times, the diplococcus intracellularis meningitidis 3 times, the staphyloccus pyogenes aureus and the bacillus of Friedländer each 2 times, and the coli bacillus, the influenza bacillus, a fine bacillus, and a pyocyanic and saprophytic bacillus each 1 time." We may recognize three groups of cases of pneumococcic meningitis:

I. *The Meningitis is a Complication of Lobar Pneumonia.* — In Montreal my attention was called to the great frequency of this association, in 8 of 100 consecutive autopsies,[16] and since these observations I have had opportunities of studying a number of cases, though I have never met with so large a proportion. By far the most important contributions to the subject

[14] Montreal Medical Journal, March, 1898.
[15] Journal of Pathology and Bacteriology, vol. v, 1898.
[16] The Morbid Anatomy of Pneumonia, Canada Medical and Surgical Journal, May, 1885, and the Goulstonian Lectures on Malignant Endocarditis, British Medical Journal, 1885, No. 1.

have been those of Nauwerck[17] and Netter.[18] Of the 29 cases analyzed by Nauwerck, in 4 the convexity of the brain was alone involved, in 16 both cortex and base, and in 7 the cortex, base and spinal cord. Netter's study, the most complete that has yet appeared, contains an analysis of 124 cases collected from the literature. In the recent monograph on pneumonia by Aufrecht,[19] 7 cases of meningitis were found in 253 autopsies, and of 1,501 cases of pneumonia, in 10 the diagnosis of meningitis was made, in 3 of which recovery followed. Of the 8 cases of pneumococcus meningitis in the department of my colleague, Welch, in only 4 was the condition associated with lobar pneumonia.

II. *Pneumococcic Meningitis from Local Infection.* — In this exceedingly important group the infection may come from the nose or the adjacent sinuses, from the ears, or may follow an injury to the skull, or an operation. In two of the three cases in the series analyzed by Dr. MacCallum there was fracture of the base of the skull. The third, a child, age six, had suppuration of the nasal mucous membrane and adjacent sinuses. In this connection the importance of the pneumococcus is universally recognized, and many cases are on record of infection from an otitis media.

III. *Primary Pneumococcic Meningitis.*— A number of observers have isolated the pneumococcus in primary suppurative meningitis. The records cannot be regarded, however, as entirely trustworthy, since it is only within the past few years that bacteriologists have learned to recognize the differences between the pneumococcus and the diplococcus intracellularis. Subsequent study must determine in what proportion of cases of sporadic meningitis the pneumonococcus exists, and in how many the diplococcus intracellularis.

The primary pneumococcic meningitis may develop in a person in good health, but more frequently there is a general pneumococcus infection in a debilitated individual, or in one with chronic disease. The meningitis may be present along, or, as is so common, in association with endocarditis. Of the cases examined in the post-mortem room of the Johns Hopkins Hospital, one (No. 989), a man, age forty-four, had a general infection with the pneumococcus and meningitis. Another case (No. 1,206), with a general infection, acute endocarditis and meningitis, is not included in this series, as a partial autopsy only was allowed, and but a small portion of the lumbar cord was examined.

CLINICAL FEATURES OF PNEUMOCOCCIC MENINGITIS.

I shall now refer to certain clinical features of these three groups of cases:

(*a*) *Pneumonia with Complicating Meningitis.*—Is the case one of cerebro-spinal fever with pneumonia or of inflammation of the lungs with an added meningitis? This question does not often arise now at the bedside, as it is most exceptional for the meningitis of pneumonia to present the symptoms of cerebro-spinal fever, and in a dubious case occurring during an epidemic the lumbar puncture (as in a case to be referred to in a few minutes) may be relied upon to clear up any doubts. The most valuable clinical record of meningitis in pneumonia is to be found in Nauwerck's paper. The histories, 17 in number, are very full and complete, and in every case accompanied with a post-mortem report. He has added a series of 12 cases from the literature, making 29 in all. All of the cases were above the twentieth year of age — a striking contrast to cerebro-spinal fever, in which a large proportion of all the cases are in the young. A second point is the latency of meningitis in pneumonia, which is much more often recognized in the dead-house than in the wards. Netter states that fully one-half of the cases are of this latent type. Of the cases I saw in Montreal I remember but one in which the diagnosis was made during life. Huguenin, referring to this obscurity, says: "We know no symptom which is constant in all cases or which may not be present in an identical manner in other conditions." Headache, early delirium, deepening into unconsciousness, are present in all cases. This is a consequence of the more common involvement of the cortex of the hemispheres. As Leichtenstern remarks, the mind may remain clear throughout the course of a case of cerebro-spinal fever. Spinal symptoms are rare; in only seven of the cases analyzed by Nauwerck was there rigidity of the neck muscles. Strabismus was present in one-fifth of the cases, ptosis only once. The importance of lumbar puncture cannot be too strongly emphasized. A recent case, which occurred while cases of cerebro-spinal fever were in the hospital, illustrates this so well that I give an abstract of it:

Charles E., age fifty-two (Hospital No. 26,417), was admitted May 6, 1899, with pneumonia of the right upper lobe of about eight days' duration. He was in a semi-comatose condition, with a temperature of only 99°, respirations 32, pulse 108. There was a pneumonia of the apex of the right lung. The day after admission it was noted that his arms and legs were very stiff; Kernig's sign was well marked, and there was some rigidity of the neck. The patient, however, responded to questions. Lumbar puncture was made in the third interspace, and 5 cubic centimetres of a perfectly clear limpid fluid obtained. Lumbar puncture was made again on May 10th, and 30 cubic centimetres of a perfectly clear fluid obtained, negative on cover-slips and culture. For the next three days he had a good deal of tremor. Kernig's sign was present, and there was still some rigidity of the arms and of the neck. The leucocytes ranged from 16,000 to 24,000 per cubic millimetre. On the 14th lumbar puncture was performed for a third time, and a slightly turbid fluid obtained, from which on cover-slips the pneumococcus was obtained. The patient died on the evening of the 14th. The autopsy showed a pneumonia of the right apex, a very slight purulent exudate at the base, some turbid fluid in ventricles, and a small amount of turbid cerebro-spinal fluid, but no positive exudate on the spinal meninges. There was an ulcerative endocarditis of the aortic valve. The pneumococcus was isolated from the meninges, the heart-valves, and from the lung. A very interesting feature in this case was the normal temperature on the 11th, 12th and 13th days of the disease, and the high temperature on the 14th and 15th days, ranging to 105° and 106°.

And lastly, a most important difference between the meningitis complicating pneumonia and cerebro-spinal fever is the almost universally fatal course of the former. Nauwerck describes the complication as invariably fatal, and he is not able to convince himself that in any one of the reported cases of recovery in the literature meningitis was actually present. Netter speaks somewhat more hopefully, and states that recovery may occur. He gives two cases from the literature, both in children. In one, a child of five, in which the crisis occurred on the sixth day, the signs of meningitis were the presence, during the first few days, of headache, unequal pupils, and ptosis. Aufrecht,

[17] Deutsches Archiv f. klin. Med., Bd. xxix.
[18] Archives Générales de Médicine, 1887.
[19] Nothnagel's Specielle Pathologie und Therapie, Bd. xiv.

in his recent monograph,[20] also speaks of the possibility of recovery. Of ten cases of meningitis in 1501 of pneumonia, three recovered. Netter,[21] in his article in the "Twentieth Century Practice," commenting upon the statement by Wentworth that pneumococcal meningitis is always fatal, states that "as early as 1887 I demonstrated, however, that its curability is one of the most evident characteristics of the pneumococcal meningitis." So far as I can gather, there is nothing in his essay to justify such a statement, since, as I have mentioned, he gives but two instances of recovery.

Personally, I have never recognized recovery in pneumonia complicated with meningitis, and the literature of the subject bears out strongly the view that one of the most striking differences between the meningitis of pneumonia and cerebro-spinal fever is the almost invariably fatal termination of the former.

(*b*) ***Pneumococcic Meningitis from Local Infection.*** — Two of the three cases in this group were surgical: one (No. 746) followed removal of the bones of nose and orbit; the other (1,151), a fracture of the base of the skull, involving the cribriform plate of the ethmoid. In both the pneumococcus alone was isolated from the exudate in the cerebral meningitis. In two of Councilman's eight cases the infection followed fracture, in one otitis media. Cases of this group do not so often appear in the medical wards, but last year we were particularly interested in a case in which the infection started from the nose and accessory sinuses, though the possibility has to be considered of extension from the meninges. An abstract is worth quoting:

Anna C., age six (black), admitted March 31, 1898. Her previous history was negative. Five days before entrance, directly after supper, she vomited and complained of headache; later in the evening she became delirious. Two days after the head was held stiffly, and she had much pain in the back of the neck. She had fever, rapid pulse, loss of appetite, and constipation. On admission she was conscious, but very irritable and difficult to examine. The head was arched back and could not be brought forward. The pupils were equal and reacted to light. There was a marked slight internal strabismus. There was nothing of moment found in the examination of the chest and abdomen. She was very tender in the suboccipital region, but there was no sign of disease of the cervical spine. Lumbar puncture on the 1st was negative. For the first week the condition remained about the same; the child could be roused, and answered questions, the strabismus persisted; there were no changes in the optic nerves. The temperature ranged from 100° to 104°. The arching of the head and neck continued; the eyes looked directly upwards. On the 17th a rash appeared, a diffuse erythema over the face, neck and chest, with papules. The rash faded in three days. The temperature ranged from 102° to 104°. On April 19th a profuse, purulent discharge appeared from the nose, which showed the pneumococcus on cover-slips, but in cultures only the staphylococcus aureus grew. She could still be roused; the attitude remained as shown in the photograph. No optic neuritis. Throughout the 18th the temperature dropped from 105° to 97° on the morning of the 19th, and continued about 97° until her death on the morning of the 21st. One of the most remarkable features was the retention of consciousness to within a week of her death.

The autopsy (No. 1,082) showed exudate over the sulci of the hemispheres. The base, from just behind the optic commissure over the pons and lateral lobes of the cerebellum, was covered with a soft yellow exudate. The posterior surface of the spinal cord showed the same. The ventricles were much distended with a turbid fluid. There was suppuration of the mucous membrane of the nose, and of the ethmoidal and sphenoidal sinuses. Cultures showed the pneumococcus in the cerebro-spinal exudate, and from the nasal pus the pneumococcus and the staphylococcus aureus.

(*c*) ***Primary Pneumococcic Meningitis.*** — Future investigations will decide the proportion of cases of primary cerebro-spinal meningitis due to the pneumococcus and to the diplococcus intracellularis; and it will be an exceedingly interesting study to determine whether there are clinical differences such as separate so decidedly the meningitis complicating pneumonia from the cerebro-spinal fever. Judging from the bacteriological records given by Councilman, Mallory and Wright, and those of the Pathological Laboratory of the Johns Hopkins Hospital, the primary pneumococcic meningitis is rare in America — certainly much less infrequent than the secondary forms. Two of Councilman's ten cases, both infants, one of ten months, the other of six days, were primary. I cannot gather from Netter's statistics [22] how many of his cases were *primary;* nor without consulting the original can one say how many of the 13 cases of sporadic meningitis studied by Malenchini (quoted by Netter) belonged to this group. Of our eight cases, as stated, only two were primary. One of these is worth quoting:

G. C., age forty-four (white), admitted at 6.30 P. M. on September 1, 1887, in an unconscious state. When seen by his brother on Saturday, the 29th, he was quite well. After going to bed on Sunday evening, the 30th, he had a severe chill. On Monday he was too ill to go to work. In the evening he became delirious, and ever since has had fever, has been restless, difficult to restrain, and very noisy. On admission the temperature was 105°; the pulse 136 and small. Dr. McCrae saw him a few minutes after he had been put to bed, and took very full and careful notes of the condition. The face was flushed and he looked distressed. There was no strabismus; the pupils were dilated and inactive. The head and neck were held stiffly, and the arms were held firmly flexed on the chest. There were no signs of pneumonia; the heart sounds were clear. The abdomen was not distended, there were no rose-spots and the spleen could not be felt; there were no herpes. The skin had a diffuse mottling, but no purpuric spots were seen. There was no urethral discharge. The leucocytes were 13,500 per centimetre, no alteration in a differential count of 500. The Widal reaction was not present. At 10 P. M. the temperature had reached 106° and he was given a bath at 80°, with ice frictions, which reduced the rectal temperature to 103°. At 11 P. M. the body seemed to be held much more stiffly. At 12 midnight he was much worse, and at 12.40 A. M. he died, about three days and three hours from the time of the initial chill.

The post-mortem (No. 989) showed a diffuse purulent meningitis of the hemispheres; the base much less involved and the ventricles not at all affected. The cord unfortunately was not examined. There was a recent diffuse nephritis, and the urine in the bladder contained albumin and tube casts. There was a general pneumococcus infection, no pneumonia or endocarditis, and the pneumococcus was separated in pure culture from the meningeal exudate.

V. NOTE ON THE TREATMENT OF CEREBRO-SPINAL FEVER.

In our series of cases we have used no special drugs. Morphia has been freely given to control the pain. Ice sponging has been employed whenever the temperature reached above 102.5°. Our mortality, considering that the cases were, as a rule, quite severe,

[20] Nothnagel's Specielle Pathologie und Therapie, Bd. xiv.
[21] Archives Generales de Medicine, 1887, 1., p. 273.
[22] Twentieth Century Practice, vol. xvi, p. 193.

has been low, only 8 of 18 cases in the hospital, and 9 among the 21 cases which I have seen.

I have already spoken of the possible benefits in certain cases of the relief of pressure by the withdrawal of cerebro-spinal fluid.

In two of our cases the spinal canal has been opened, drained and irrigated. Winter,[23] in tuberculous meningitis, removed the spinal process of the second lumbar vertebra and drained the spinal canal. Von Ziemssen first attempted to use local therapeutics to the membranes of the cord by injecting a weak solution of iodine in a case of meningitis; and later Sahli practised permanent drainage through a canula and catheter. So far as I know, an extensive laminectomy had not been done for acute spinal meningitis until our first case, November 6, 1898, in which the operation was suggested and performed by Dr. Harvey W. Cushing, the first assistant in the surgical clinic of my colleague, Professor Halsted. The case has already been given in abstract under the section on bacteriology[24] as the one in which the staphylococci only were present at the time of operation. The spinal canal was thoroughly irrigated with salt solution and a quantity of purulent exudate washed out. No change followed in the existing paraplegia. The bladder and the kidneys became infected, and he died about two months after the operation. The paraplegia persisted. At autopsy the spinal meninges were smooth and looked perfectly normal. It was impossible to say where the dura mater had been incised, and there were neither adhesions nor areas of thickening on the pia-arachnoid. There were extensive changes in the cord itself and in nerve roots.

In Case 12 laminectomy was performed on the 4th day by Dr. Cushing. The patient was very ill, and the spinal symptoms were especially pronounced. A catheter was passed beneath the dura mater, and the membranes drained and irrigated with salt solution. For several days he seemed much better. He developed a hemorrhage, cystitis and pyelonephritis, and died on the sixth day after operation.

Dr. Musser, of Philadelphia, has also had an unsuccessful case. Dr. Rolleston and Mr. Herbert Allingham have reported[25] a case of sporadic cerebro-spinal meningitis in which the patient recovered after laminectomy and drainage. On the principle of a desperate remedy for a desperate disease, the operation (which has been criticised adversely in an editorial note in the *Philadelphia Medical Journal*) seems justifiable in certain severe cases, in which, as in our first case, the spinal symptoms were very marked.

OFFICERS OF THE NEW JERSEY STATE MEDICAL SOCIETY. — At the meeting of the Medical Society of the State of New Jersey held at Allenhurst, June 27th, 28th, and 29th, the following officers were elected for the ensuing year: President, Dr. Luther M. Halsey, Williamstown; Vice-Presidents, Drs. William Pierson, Orange, John D. McGill, Jersey City, and E. L. B. Godfrey, Camden; Corresponding Secretary, Dr. E. W. Hedges, Plainfield; Recording Secretary, Dr. William J. Chandler, South Orange; Treasurer, Dr. Archibald Mercer, Newark.

THE EXAMINATION OF STAINED SPECIMENS OF BLOOD IN ITS APPLICATION TO CLINICAL WORK.[1]

BY HENRY F. HEWES, M.D., BOSTON.

THE utilization of the examination of the blood as an aid to diagnosis in ordinary clinical work is far less common than its value in this regard warrants. This is due primarily, in my opinion, to the almost total inexperience of practitioners in general in the practical application of this method of clinical diagnosis. Most physicians' blood-learning is entirely from the books, and there is consequently an almost total lack of exact knowledge in regard to the appearances of the blood, and the interpretation of these appearances in the various pathological conditions, where they may have special significance.

One cause of this failure of many physicians to acquire this experience in blood examination is an exaggerated idea of the complexity of the methods involved. For this incorrect idea in regard to the complexity of the technique and the amount of labor necessary to obtain the required information from blood examination we have to thank the text-books. In the chapters upon blood examination contained in most of these books, the greatest prominence is given to the description of those methods of work involving the possession of expensive apparatus and the output of much labor, as the blood counts or colorimetric methods, while some of the simpler and much more useful methods, as the examination of a stained specimen, are given but secondary attention, or at least their wide applicability to general work is not indicated.[2]

It is frequently said that the value of the results obtained from a blood examination is in most cases not in proportion to the labor involved in obtaining them, so that the use of the blood examination as a routine method in clinical work is not to be thought of. And this would be true if we had to depend upon all these methods for all our information concerning the blood.

But as a matter of fact such is not the case. A large per cent. of all the information which we can obtain from the blood in a majority of cases can be obtained by the application of a single method, and one so simple in its technique that it can be applied by any practitioner who owns a microscope. This method is the now well-known one of examination of a stained specimen of the blood.[3]

This method has been in the general mind relegated to the use of specialists, and its application confined to the diagnosis of the severe affections of the blood, the severe anemias and leukemias. In reality its use is by no means confined to these conditions. The results obtained from its application may be of value in a considerable number of the common conditions met with in regular practice, as in the disclosure of the existence of an anemia, a leukemia or other form of leucocytosis, or of malaria. And its application is simple to any one who has had training in it.

[1] Introductory lecture to the course in hematology at the Harvard Medical School.
[2] Ehrlich's latest publication upon the subject, "Die Anæmie," is not open to this criticism, as here the study of stained specimens is given due prominence. Die Anæmie: Ehrlich u. Lazarus. Specielle Pathologie u. Therapie, Nothnagel, Bd. viii., Theil 1, H. 1.
[3] There are two kinds of blood staining, the staining of moist films and of dry films; the former is used in histological study, the latter only is used in clinical work.

For this application there is necessary at the bedside simply a few clean seven-eighth-inch cover-slips and a needle, which articles every practitioner can carry regularly.

The blood is spread upon these cover-slips, and dried in the air. The slips are then taken to the office and at any time within a few days fixed by heating at 110° C. for ten minutes or by placing in some fixing solution (as absolute alcohol, alcohol and ether, or corrosive sublimate), and stained.

There are several methods of blood staining which may be used, the special method employed being dependent to some extent upon the special purpose for which the blood is stained. For general work the following modified Ehrlich staining method gives the most satisfactory results for all purposes. The blood, which has been properly fixed, is subjected for four minutes to an Ehrlich three-color mixture, prepared according to the following formula:

Ehrlich-Biondi-Heidenhain, three-color mixture	1.7 grammes
Acid fuchsin	0.05 grammes
Absolute alcohol	2 c. c.
Distilled water	13 c. c.

The specimen is then washed in water and subjected for from one-half second to ten seconds to Löffler's solution of methylene-blue (saturated alcoholic solution of methylene-blue, 30 cubic centimetres, potassic hydrate [1–10,000 solution], 100 cubic centimetres). The specimen is then again washed, dried and mounted in balsam.[4] It may then be submitted to microscopic examination.[5]

In a majority of cases this examination will serve to definitely rule in or rule out the existence of a pathological condition of the blood and to determine the nature of this condition. Then if pathological conditions are found about which more definite knowledge is desired, or if any doubt remains in regard to the blood in the case, the examination may be reinforced or continued by the application of the other methods, the blood counting and the hemoglobin estimation. Otherwise we may rest on the finding of the stained specimen.

[4] The reason for this addition to the original Ehrlich method, this application of an alkaline basic stain following the application of the regular Ehrlich mixture, is as follows: We wish by the stain to bring out a differential staining of the protoplasm of the leucocytes which shall allow of the classification of each leucocyte under one of three headings in accordance with which of the three staining reactions, acid, neutral or basic, it takes. A study of the staining affinities of the constituents of cell protoplasm shows that the acid elements stain more clearly in an acid solution, the basic stain more clearly in an alkaline (often not at all in an acid), the neutral best in a neutral or slightly acid solution. Clearly, all three reactions cannot be brought out to the best advantage by the use of a single staining mixture, since this cannot be both acid and alkaline. At best a single mixture can be neutral, and in a neutral mixture the basic elements of the protoplasm do not stain strongly enough. The original Ehrlich mixture has a neutral or slightly acid reaction. It can be used, therefore, for obtaining the neutral and acid reactions in the leucocytes, and is in fact the best neutral staining mixture that we possess. It is not so useful, however, for the obtaining of the basic protoplasm reactions, but frequently fails entirely to bring these out (H. F. Hewes: Classification of the Leucocytes, Journal of Boston Society for Medical Sciences, February, 1898). To bring out these basic reactions as strongly as the others in our blood, we, therefore, apply separately a basic stain in alkaline solution. See in this connection A. Matthews: Chemistry of Cytological Staining, American Journal of Physiology, vol. 1, No. 4. This author shows that one of the chief constituents of cell protoplasm, albumin, stains with basic stains strongly in an alkaline solution, but faintly, or not at all, in neutral or acid solutions.

This is one of several illustrations of the principle upon which the modified Ehrlich method is based, the principle that the affinity of cell elements for a given stain is dependent upon the reaction of the staining solution.

In addition to thus aiding in the differentiation of the leucocytes this modified method has the further advantage over the old method that it makes the distinction between nucleated red corpuscles and basophilic leucocytes (lymphocytes) much more clear, also that it stains malaria organisms.

[5] For the microscopic examination a one-tenth or one-twelfth oil immersion lens should be used. With practice a seven Leitz, or any lens of corresponding power, can be substituted for the immersion, but observation with the higher power is much more satisfactory.

For the application of this method of the study of blood to clinical work there is necessary, besides a certain facility in this process of preparation of the specimens, a certain amount of training in the examination of specimens of normal and pathological blood prepared by this method.

The first requisite is a thorough familiarity with the appearance of stained specimens of normal blood. If we study a good stained specimen of such blood we shall see that the specimen contains two forms of corpuscular elements, the red corpuscles, which are round, yellow-stained, disc-shaped plastids, and the white corpuscles, which are nucleated, granular cells taking varieties of stains according to their kind. The red corpuscles will be practically all of a round or slightly oval shape, of a uniform size, the diameter varying from 6 to 9μ, and of the same intensity and reaction in color. The centre of each corpuscle will appear as a white zone of a definite size.

This uniformity in shape, size, color reaction, and in the size of the white centre of the red corpuscles is a striking and important characteristic of a specimen of normal blood. It is so regular that a general lack of such uniformity in a given specimen may in itself be taken as conclusive evidence of the existence of a condition of anemia. A few degenerate forms will of course be found in every specimen, since there are always some corpuscles dying and disintegrating in normal blood, but they are so few as to be scarcely noticeable. The uniformity is maintained of course only in fields where the spreading is perfect. In parts of every cover-slip there will be seen corpuscles of irregular form, without the white centre or biconcave appearance. These are simply the results of injury in the method of preparation of the specimen. They are flattened or all drawn out in one direction, and can easily be distinguished from corpuscles which are naturally abnormal.

The white corpuscles appear as granular nucleated cells of varying size, but as a rule larger than the red corpuscles. The number of these white corpuscles upon a full thin spread in which the red corpuscles lie separately will vary, corresponding to the number in blood and the thickness of the spread. An average normal specimen contains 200 to 400. The comparative frequency of these leucocytes in normal slides becomes fixed in the mind after some experience in this examination, so that one can judge with fair accuracy from running over one of these slides whether the number is normal or increased in the blood. One may even by a careful count of fields measured by a measured eye-piece form an accurate estimate of the actual proportion of the white corpuscles to the red and consequently, unless the red corpuscles show evidence of marked anemia (which would suggest a diminution in their number), an estimate of the actual number of leucocytes in the blood.

Three varieties of white corpuscles can be distinguished, the basis of distinction being the staining reaction of the protoplasm when subjected to a triple stain.[6]

These three varieties are named respectively neutrophiles, basophiles and oxyphiles in accordance with the neutral, basic or acid stains of the granules or structural substances contained in their protoplasm.

The most common form will be a cell usually two or three times the size of a red corpuscle, containing a

[6] A stain containing active basic, neutral and acid principles.

blue polymorphous neucleus — often *apparently several* nuclei, surrounded by a protoplasm studded with small irregularly-shaped lilac-colored granules — the so-called *neutrophile:* the *polymorphonuclear neutrophile* — the *polynuclear neutrophile.*

The next form in point of frequency is a cell varying in size from that of a red corpuscle to four times this size, containing a blue, usually round nucleus surrounded by a protoplasm studded with fine blue granules — the *basophile.* In this class are included the lymphocytes, large mononuclear transitional forms, and mast cells of Ehrlich.

The third form is a cell of the size of the neutrophile, with a blue polymorphous nucleus and a protoplasm studded with granules of large size, regular and a golden-red color — the *oxyphile,* the so-called eosino phile.[7]

If these white cells are counted differentially as neutrophiles, basophiles and oxyphiles, it will be found that the three varieties are present in certain definite proportions in normal blood. Thus if enough cells to make a fair average be counted, say 500 or 1000, 60 per cent. to 75 per cent. will be neutrophiles; 20 per cent. to 35 per cent. basophiles; ½ per cent. to 5 per cent oxyphiles.

These limits in the differential proportion of the leucocytes hold for adults only. In children under ten years of age the basophiles are more and the neutrophiles less numerous.

These characteristics of normal blood which we have described are constant. Any general variation from them in a blood specimen is a sign of abnormality. When, therefore, the picture of the normal specimen and its limit of variation are once fixed in the mind, the determination of whether the blood in a given case is normal or abnormal is, as far as the appearance of its corpuscular elements goes, a simple matter.

Thus if the red corpuscles of our specimen are pale and their centres larger than our normal type, or if the characteristic uniformity in size or shape be lacking, we are at once aware that the blood in hand is not normal; or if the leucocytes are more numerous upon our slide than the rule, or the differential proportion not regular, we come to the same conclusion.

Having determined this fact, that some abnormality is present, the next point is to determine the particular significance of the special blood picture in hand. To establish this point, some experience in the study of the appearances of blood in pathological conditions is necessary. As a result of this study we find that the changes which occur in corpuscular elements of blood in disease may be divided into two classes:

(1) Changes in the characteristics of the red corpuscles, their number, or structure, or color richness, staining reaction, etc.

(2) Changes in the characteristics of the white corpuscles, their number, differential proportion or type.

The changes of the first class are expressions of a general condition known as anemia.

The changes of the second class are, as far as their value in diagnosis goes, expressions of a general condition known as leucocytosis.

Practically, therefore, the study of the pathology of the blood corpuscles means a study of the anemias and the leucocytoses.

[7] The appearances of these leucocytes here described are those present when they are subjected to the special method of triple staining described in this paper, p. 30.

Anemia, as the term is used from a clinical standpoint, means any loss of corpuscular substance in the red corpuscles. Such a loss of substance is of course associated with some changes in the structure or number of the corpuscles. Such a change involves as a direct result some alteration in the appearance of the corpuscles. The consequent loss of functional capacity of the blood or the disturbance of the blood-forming centres may result in the appearance of new and strange corpuscular forms in the blood.

For purposes of clinical work these changes which occur in the corpuscles in anemia and the abnormal forms which result from them may be to some extent classified.

(1) We have the diminution in the hemoglobin content of the corpuscles, as evidenced by the paleness of the corpuscles and the increased size of their white centres. This is called *achromia* and the changed corpuscles are achromic forms.

(2) We have the abnormal variation in the shape and the size of the corpuscles, evidenced by the appearance of pear-shaped, oval or triangular forms, of corpuscles smaller and larger than normal.

This condition is known as *poikilocytosis* and the irregularly shaped and sized forms are known as poikilocytes. Some observers divide the poikilocytes into three classes. All forms of a size under the normal limits are called macrocytes, all over these limits macrocytes, while the term poikilocytes is retained for the forms of abnormal shape alone. Such a division may be of use for purposes of instruction, but for practical work it is necessary to recognize simply the presence or absence of the condition of poikilocytosis, the degree of this condition, and whether an average increase or decrease in size of the corpuscles is a prominent feature of this poikilocytosis.

(3) There are forms in which the stroma of the corpuscles has in addition to its normal acid-staining elements, elements taking the blue basic or purple neutral stain. These are called polychromatophiles.

(4) There are forms not necessarily coming under any of the above headings, in which the stroma appears disintegrated and coloring matter irregularly distributed.

Many of these forms thus classified represent corpuscles which have undergone some process of necrobiosis or degeneration. Such are the achromic forms in which the normal content of hemoglobin is lacking, or the misshapen poikilocytes and small microcyte fragments, or the polychromatophiles, and some of the large macrocyte forms.

Some of these forms of abnormally large size may, however, represent not degenerate forms but corpuscles produced as the result of an abnormal process of regeneration which occurs in the blood-forming centres as the result of pathological changes. Such are perhaps the large corpuscles which occur in so great numbers in pernicious anemia, associated with the megaloblast.

(5) In addition to these evidences of degenerative changes of red corpuscles, this poikilocytosis or achromia, which we find in anemia, there are certain other varieties of red cells abnormal to the circulating blood, which we find in certain pathological conditions, principally those associated with marked anemia. These are the nucleated red corpuscles or *blasts.* These blasts appear, as they are, as red corpuscles containing one or more nuclei. In stained specimens

the stroma takes the golden acid stain peculiar to the red corpuscle, the nucleus, the blue basic nuclear stain peculiar to all nuclei.

The blasts which are found in pathological blood may be separated into three varieties:

(1) We have *normoblast*. This is a cell of the size of the normal red corpuscle, consisting of a stroma containing hemoglobin, staining golden color, containing one or more compact homogeneous deeply bluish-black staining nuclei. The nucleus is as a rule single, lies sometimes excentrically, sometimes concentrically, occupying from one-fourth to three-fourths the whole corpuscle. Its stain is much deeper and more homogeneous than that of the nuclei of white corpuscles.

(2) We have the *megaloblast*. This is a red cell of a size larger than normal, containing one or several nuclei.

The color of the stroma is as a rule less intense than that of the normoblasts. The nucleus stains blue; as a rule it stains less deeply than that of the normoblast and less homogeneously, showing a chromatin network in its substance. It may occupy from one-eighth to three-fourths of the cell. Its compact form and clear demarcation from the surrounding stroma serve to distinguish it from the nuclei of white corpuscles.

(3) *Microblasts* are nucleated red cells of a size smaller than the normal. The nucleus takes the deep color of that of the normoblast and has but little stroma about it.

The normoblast is the parent cell of the red corpuscle. It is found in great numbers in the red marrow of the bones, but never in health after the first year of life in the circulating blood. In the marrow it gets rid of its nucleus by absorption (Papenheim) or extrusion (Ehrlich) and appears in the blood as the normal corpuscle.

The megaloblast is not found in the red marrow of the normal individual. It is found in the marrow and blood-forming centres of the embryo and represents a stage in the formation of the red corpuscle here, as does the normoblast in extra-uterine life.

Blasts are found in the blood principally in conditions of anemia. They may, however, occur in the blood of conditions in which there is some lesion of the blood-forming centres, as the leukemias, even where no evidences of anemia, that is, of degenerative corpuscular changes, are apparent. The presence of blasts in an anemia suggests a severe or an advanced condition or type, an anemia in which the loss of corpuscular substance is so great as to call for very active regeneration processes in the blood-forming centres. When the blasts are exclusively normoblasts we have an evidence that regeneration is proceeding in an excessive but normal manner. When megaloblasts are present, however, we have evidence that the blood centres have reverted to some extent at any rate to the embryonal method of blood formation.

This evidence of reversion is always a sign of serious significance. The chances of recovery of an anemia in which this change has occurred are, independently of the cause of the anemia, less than those of an anemia in which regeneration is still taking place according to the normal type. Owing to this difference in the significance of the normoblast and megaloblast their differentiation in the blood becomes a matter of great importance. As a rule it is simple, if the characteristics of the two cells, the size, the homogeneous deep-colored nuclei of the normoblasts, or the rich in chromatin structure, lighter-colored nuclei of the megaloblasts, be held in mind. Where the size or the structure leaves one in doubt, the associated conditions of the blood may be of aid. The megaloblasts are commonly associated with an average increase in the size of the red corpuscles of the blood, with the presence of numerous macrocytes. So true is this association that the fact of finding a general increase in the size of the red corpuscles always leads one to suspect and look for a megaloblast anemia.

Any or all of these pathological varieties of red corpuscle, these blasts and degenerative forms may be present in an anemic blood. By studying the general picture in a given case and sorting out the varieties of changes present, we can establish not only the existence of an anemia but also the severity and type of anemia present. This differential study we shall take up later.

(To be continued.)

X-RAY EXAMINATIONS IN CHILDREN.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

In one of my early articles,[1] "The Adaptation of the X-Rays to Medical Practice," I pointed out the value of x-ray examinations in young patients, and further experience with them urges me to emphasize the usefulness of this method still further. Children and infants are more easily penetrated by the x-rays than adults, and like older persons may be readily examined without removing the clothing, as they lie on the stretcher in front of the apparatus. Infants often go to sleep while on the stretcher and may be then examined with the fluorescent screen or an x-ray photograph may be taken without disturbing them. Not only is the thorax of children more accessible to this method of examination than that of adults, but so also are the abdomen and head. In examining the thorax indeed care must be taken to avoid too much light, for the organs in the chest of a young child are so easily traversed by the rays that otherwise the border of the heart, for instance, might not be well defined because the edges are penetrated by the rays and if so the shadow of the heart cast on the screen would be smaller than the heart itself.

In some cases of pneumonia, especially in the early stages, we cannot detect the presence of pneumonic areas in infants and children, nor in adults, and in these cases a doubtful diagnosis may be made more certain by an x-ray examination. For example, I recall a child, six years old, in one of the wards of my service at the Boston City Hospital, with a high temperature, a leucocytosis (25,000), pain and stiffness in the back of the head and neck, the neck so rigid it could not be flexed. There was no history, and no physical signs were found in the chest after a careful examination by two admitting physicians. My house physician also found nothing in the lung, and I was inclined to accept the diagnosis of cerebro-spinal meningitis which had been made by the three physicians who had seen the patient. I made an x-ray examination, however, in order to obtain further information,

[1] Medical and Surgical Reports of the Boston City Hospital, January, 1897.

and found a dark area over one lobe and a shortened excursion of the diaphragm on that side, and the diagnosis of pneumonia was made without hesitation. This diagnosis was confirmed by a marked crisis, and rapid clearing of the lung, as determined by x-ray examinations. At no time during the course of the disease did I obtain signs of consolidation by auscultation and percussion.

Again, in young patients with symptoms which suggest tubercular meningitis it may be desirable to have a careful x-ray examination of the lungs, with a view to determining whether or not tuberculous foci exist there.

In pleurisy, with effusion or empyema, the x-rays assist very much in the diagnosis; any condition of the lung which would make this organ less penetrable by the rays than normal, or where the excursion of the diaphragm might be changed, would be easily observed. Changes in the size, position or shape of the heart — and some of these conditions are not readily detected by the usual physical examination — are very definite and patent to the x-rays.

The size and position of the liver and spleen are more readily determined in children than in adults; likewise the size and position of the kidneys, especially the left one.

The size of the stomach, by giving subnitrate of bismuth with bread and milk, may be determined, and the changes in size and shape after a meal may be followed. The changes in the size and shape of the stomach of a child have thus been watched during the process of digestion by Mr. W. B. Cannon and myself. These observations are still unpublished.

In a word, I wish to direct attention to the advantages which young patients offer to this method of examination, in the hope that it may assist in arousing more appreciation of its usefulness, not only in examinations of the thorax but also in ascertaining more exactly the conditions present in other parts of the body.

There need be no fear of untoward effects from x-ray examinations if simple precautions are taken. I have never had any in the about three thousand examinations that I have made.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

MEETING OF THE SECTION ON SURGERY AND ANATOMY, COLUMBUS, O., JUNE 6, 7 AND 8, 1899.

THE first session of the Section in Surgery of the American Medical Association was "appendicitis day," there being eight papers read upon that subject.

In the address of the Chairman, DR. W. J. MAYO, of Rochester, Minn., upon

CICATRICIAL STRICTURE OF THE ESOPHAGUS AND ITS SURGICAL TREATMENT,

the author said that esophageal obstruction was a subject that must command the attention of every thoughtful surgeon; that the inaccessible situation of the gullet, its relation to important structures and the difficulty attending manipulations within its narrow lumen, all tend to place it among the surgical problems difficult of solution.

CONSIDERATIONS ON THE DIAGNOSIS AND TREATMENT OF GALL-STONES.

DR. JOSEPH RANSOHOFF, of Cincinnati, read a paper on this subject. He said that cholecystotomy was first done by Boggs in 1868, and that it was not made a formal operation until ten years later by Marion Sims. Concerning the etiology of gall-stones comparatively little is known, and experiments made to produce them around foreign bodies introduced into a normal gall-bladder had almost always failed. Gall-stones present but few varieties, the vast majority being formed either by pure cholesterin or of bile pigments. Cholecystenterostomy had a limited field of application, that is, obstructive jaundice from malignant disease or impermeable cicatricial stenosis of the common duct.

DR. A. J. MCCOSH, of New York City, read a paper entitled

OBSERVATIONS ON THE TREATMENT OF GALL-STONES.

He said that it was believed by many that so-called biliary colic was not produced so much by the passage through or impaction of a calculus in the bile passages as by inflammation of the gall-bladder and ducts, and that as long as the bile and the biliary passages remain normal a gall-stone would, as a rule, produce but few symptoms. He thought that one stumbling-block which was often found in the path towards a correct diagnosis was the idea that if a stone was impacted in the common duct the result would be a distended gall-bladder. His paper was a very exhaustive one and dealt at length with the citation of individual cases.

In discussion, DR. WALKER, of Detroit, spoke of drainage, and said that in his operations of late he had been in the habit of closing the gall-bladder and letting it fall back into the abdomen. He had no trouble in utilizing the purse-string suture.

DR. BEVAN, of Chicago, thought that a great deal was known of the etiology of gall-stones; that he always looks for a history of typhoid or intestinal infection, and that in a number of cases he had found typhoid bacilli in the gall-bladder of patients. He advised the S-shaped incision, which he had previously reported.

DR. MORRIS, of New York, illustrated a method of closing the gall-bladder.

DR. MURPHY, of Chicago, Ill.; DR. FERGUSON, of Troy, N. Y.; DR. THOMAS, of PITTSBURG, Pa.; DR. PORTER, of Fort Wayne, Ind.; DR. WARREN, of Columbus, O.; DR. RODMAN, of Philadelphia; DR. MOORE, of Minnesota; and DR. MARCY, of Boston, followed in discussion.

DR. W. E. B. DAVIS, of Birmingham, Ala., reported a case of obstruction of the gall-bladder and common duct, in which a stone was not found, occurring in a pure negro, age seventy.

DR. A. J. OCHSNER, of Chicago, read a paper on

APPENDICITIS AS A CAUSE OF INFLAMMATION OF THE RIGHT OVARY AND TUBE.

He said that during the past five years surgeons had frequently observed the fact that appendicitis might occur in patients suffering from an inflammatory condition of the ovaries and tubes; that most of these observers had found difficulty in making a differential diagnosis. He was of the opinion that appendicitis was frequently the cause of inflammatory disease of the right ovary and tube, and occasionally the left, and

that such a condition was likely to give rise to a chronic invalidism, owing to the periodic exacerbation resulting from congestion due to menstruation; that in operating for chronic or recurrent appendicitis in patients suffering also from dysmenorrhea the right ovary and tube should be examined.

COMPLICATIONS AND SEQUELÆ OF APPENDICEAL ABSCESS.

DR. JOHN B. DEAVER, of Philadelphia, read this paper. He said, in part: Of all the complications of appendicitis, peritonitis, that dreadful disease which has and is to-day carrying many a human soul into eternity, stands foremost in frequency and mortality. One, if not the most, distressing sequel of appendiceal abscess is a fecal fistula. The surgeon is too frequently held accountable for this terrible condition. I style it terrible, for I know no word that can better express it. Gentlemen, I repeat to you, appendicitis with pus-formation produces ravages of the worst description, the effects are often permanent and irremediable, and in my experience unequalled by any other affection occurring within the abdominal cavity. For me the lesson taught by the widespread disastrous lesions of appendiceal pus was long ago learned. In fact, these very complications but accentuate the necessity for early operation to usher in that prevention which is indeed cure. Would that my voice were strong enough to sound the note of warning against delay in the presence of appendiceal pus, its ravages, etc., from the Atlantic to the Pacific and far beyond, and from the Everglades of Florida to the glaciers of Alaska.

DR. ROBERT MORRIS, of New York, read a paper on

BAD METHODS IN APPENDICITIS.

He said: I say, shame upon any member of the profession to-day, no matter who he is or where he lives, who allows an appendicitis patient to become a chronic invalid and unfit to follow any occupation, provided he is in reach of intelligent resources.

ANATOMY AND BIOLOGY OF THE PROCESSUS VERMIFORMIS.

DR. G. G. EITEL, of Minneapolis, read this paper by title.

DIAGNOSIS AND TREATMENT OF APPENDICITIS, WITH REPORT OF 102 CASES.

DR. MEANS, of Columbus, read this paper. He said that of the 102 cases reported 45 were in females and 57 in males. In 9 cases operation was made within twenty-four hours after the attack. It had been his observation rather than his experience that when there was profound septicemia, complete paresis of the bowel, with a pulse-rate entirely out of proportion to the temperature, an operation was useless. He believed that few diseases had a more uniform set of symptoms than appendicitis. He further stated that the controversy that has been waged during the last decade as to whether appendicitis should be classed as a medical disease, a mixed disease, or a surgical disease, has been decided largely in favor of the surgeons. He maintains that it is the consensus of opinion of the profession to-day that appendicitis is essentially a surgical disease, and should be treated from that standpoint. He did not believe that the time for operation depended altogether upon pathologic conditions as found in the patient at the time of the first visit. Early operations gave the best results.

DR. WILLIAM H. HARSHA, of Chicago, considered

INQUIRIES IN THE ETIOLOGY AND TREATMENT OF APPENDICITIS.

He thought that among the etiologic factors was age, appendicitis being essentially a disease of the young. A study of 157 cases occurring in some of the Chicago hospitals during the past year shows an average of twenty-six years, the oldest patient having been sixty-two and the youngest one and one-half years old. Continuing, he said: The greater frequency in males is no doubt due to their greater exposure to injury, fatigue, colds and over-indulgence in eating and drinking. The seasons affect materially the frequency of attacks, the greater number occurring during the summer months.

In discussion, DR. KEEN, of Philadelphia, said, in part: Dr. Deaver, if I understand him rightly, considered a general suppurative peritonitis is a contra-indication to operation. The very fact that a patient has a general purulent peritonitis as a result of appendicitis means to me instant operation and thorough operation, for this very reason, that if you let such a patient alone he is just as absolutely sure to die as he is sick; that the majority of those who are taken with a suppurative peritonitis will die, operation or no operation, is certainly true, a majority of them, but every one rescued is rescued from the grave, and that those cases are not without hope I am absolutely certain, both from reading and from experience, for I could recount at least four or five cases in my own practice, in which life has certainly been saved simply by the ordinary operation for appendicitis and by an operation on both sides, which would allow thorough flushing out, complete cleansing of the abdomen as far as can be done.

DR. MURPHY, of Chicago, then took the floor, and in a question-and-answer form discussed with DR. KEEN the time for operating in all appendicitis cases.

Eventually many interested members joined in a lively discussion. They were: DR. LEWIS, of Kansas City; Dr. GRANT, of Denver; DR. JOHNSON, of Hartford; DR. WAGNER, of Chicago; DR. LAPLACE, of Philadelphia; DR. PORTER, of Fort Wayne.

DR. EMIL RIES, of Chicago, Ill., read a paper entitled

SOME RADICAL CHANGES IN THE POST-OPERATIVE TREATMENT OF CELIOTOMY.

In the animated discussion which followed, interesting points were adduced by DR. MANLEY, of New York, and DR. BONNAFIELD, of Cincinnati.

SECOND DAY.

DR. A. I. BOUFFLEUR, of Chicago, Ill., read a paper on

DERMOID FIBROMA OF THE ABDOMINAL WALL AND PLASTIC OPERATION FOR SUCCESSFUL REPAIR OF DEFECT CAUSED BY ITS REMOVAL.

OBSERVATIONS ON PREVENTION OF SURGICAL SHOCK AND COLLAPSE, BASED ON CLINICAL AND EXPERIMENTAL EVIDENCE.

DR. GEORGE W. CRILE, of Cleveland, O., read this paper. He said: Experimentally, as well as clinically, the brain cannot withstand long pressure; it produces shock by interference with the vasomotor system. Collapse may be produced on the brain by direct press-

ure, and interference with respiratory centres, which it has been shown are located on the base. In operations on the brain, in the presence of abscess or hemorrage, or in the presence of intracranial pressure, it is necessary to give the patient a hypodermic injection of atropia. It guards the heart against the inhibitory action of the vagi. In operations on the neck he stated that experimentally he had been able to show that when the laryngeal mucosa had been subjected to treatment of cocaine, this drug had an absolutely inhibitory effect on reflex action; that in any given case of operation on the neck, if the patient is given physiologic doses of atropia before the operation is begun, and if at the same time the laryngeal mucosa is properly treated with cocaine, it is impossible, as long as these drugs have their effect, to produce collapse in any such operation. In reference to opening joints, Dr. Crile said that, as a matter of fact, there is no nerve supply in a joint that is capable of producing collapse or shock to a great degree, but that the shock produced in operations on the extremities was caused by cutting of nerve tissue, a large nerve trunk — a great bungling; sawing through the anatomic bone with the periosteum intact produces but a small amount of shock.

In discussion, DR. LEAVING, of Milwaukee, said that in the matter of prevention of shock the physical and mental condition of the patient preceding the operation and at the time of operation was of importance; patients should be in the best possible condition. He was in the habit of putting his patients for two or three days before an operation under the influence of strychnine, because of its support to the heart during the time of operation and to the nervous system and heart subsequently. He thought also that the rapidity of the operation was a large factor.

DR. ALLEN, of Cleveland, thought that as little time as possible should be lost in the operation and that as little blood as possible should be lost. He believed that temperature was an important element. He recited some interesting experiments performed on dogs in a very warm room.

DR. O. OCHSNER, of Chicago, mentioned, as other factors in shock, traumatized tissues, superfluous number of stitches, the unnecessary manipulation of the tissues.

DR. BULLETT, of Louisville, presented a differentiation between traumatic shock or shock arising from railroad injuries and that caused by hemorrhage or loss of blood incident to accident.

DR. MURPHY, of Chicago, said that the operator who makes a clean, rapid operation, without injury done, without traumatism, is the operator who takes his patient off the table in a good condition.

DR. DAN MILLIKEN, of Dallas, Tex., referred to a brother practitioner in Sherman, who found that thoroughly washing out the stomach, or performing lavage, thus removing all mucus or foreign material, lessened to a great extent the amount of shock.

DR. ARTHUR D. BEVAN, of Chicago, read a paper on

OPERATION FOR UNDESCENDED TESTICLE AND CONGENITAL HERNIA.

He said that the malposition of the testicle is often complicated with hernia, and hernia of a very dangerous and distressing type. When the testicle is retained high up in the abdomen and does not reach the internal abdominal ring, a hernia is not very apt to coexist, but in one-half of the cases when the testicle is in or about the inguinal canal a hernia is present. It is difficult to retain such a hernia with a truss, because the pressure upon the testicle is unnatural, and such pressure is apt to produce traumatic inflammation of the organ. A retained testicle in or about the inguinal canal is peculiarly liable to injury, both external injury from its exposed position, and also injury from bodily movements, exercise of any kind in which the abdominal muscles are strongly contracted, sneezing and coughing. He had had one case in which the patient was compelled to remain in bed whenever he had a slight cold because the pain of coughing and sneezing was excruciating.

Why should we refuse the cryptorchid the benefits of a surgical procedure which, if properly done, is as safe and sure as a Bassini hernia operation, and which is of much more value to the individual, both from a physical and mental standpoint? He desired to refer to the best method of handling the vaginal process of peritoneum in operations for congenital inguinal hernia. He had until recently been in the habit of obliterating the vaginal process in these cases by a purse-string suture at the internal ring, and by whipping up the peritoneum around the cord with a continuous catgut suture, leaving enough to form a tunica vaginalis. In a careful dissection of a case of inguinal hernia he found that when, as it was very difficult to separate the vaginal process from the cord proper, he opened widely the inguinal canal, so as to expose freely the internal ring, he could very easily separate the peritoneum from the cord, just where the cord separates into its constituent elements, where the vas turns inward and downward and the spermatic vessels pass upward. Here he could readily separate and cut off the vaginal process and close the abdominal cavity, as in treating the sac of an acquired hernia. Further, he found that by following the vas and spermatic vessels inside of the abdominal cavity with his finger, and freeing them from the peritoneum covering them, he could pull them a surprisingly long distance out of the abdominal cavity. Since that time he had had an opportunity of operating on four cases of congenital inguinal hernia, which he had handled in this way: An incision three inches in length was made over the inguinal canal. He then proceeds by splitting up the entire length of the canal, exposing freely the internal ring, opening the vaginal process, freeing the vaginal process high up, where the vas and spermatic vessels separate, ligating the vaginal process with catgut at the internal ring and dividing a half-inch below the ligature. Then, without stripping the vaginal process from the entire length of the cord and without removing any of it, he continued by throwing a catgut ligature around it and ligating so as to close it, forming a large tunica vaginalis.

In discussion, DR. MILLIKEN, of Dallas, TEX., thought the operation for castration should be performed from eight to ten years of age; that fifteen was a little too late.

DR. LORD, of Omaha, reported a case of metastatic inflammation of the testicle.

DR. HARRIS, of Chicago, thought the two factors involved were (1) the necessity of an operation; and (2) the functional capacity of the organ. He did not think it was advisable to operate these cases previous to the age of puberty. He had removed a number of

testicles, and in cases over twenty-five no living spermatozoa could be found.

Dr. McArthur thought that no testicle should be extirpated until extraperitoneal reposition of that testicle had been tried.

Dr. Shaffer, of Chicago, was of the opinion that the operation for castration should not be performed until the age of puberty.

Others who took part in the discussion were Dr. Bouffleur, of Chicago; Dr. Manley, of New York; Dr. Reed, of Rock Springs, Wyo.

The morning session closed with the reading of a paper by Dr. Elliott, of New York, entitled

CONTRIBUTION TO THE TREATMENT OF SPINAL CARIES.

The afternoon session opened with two papers on

EXSTROPHY OF THE BLADDER.

Dr. Dudley A. Allen, of Cleveland, in his paper, said: All methods which have been introduced for the formation of a covering for the exposed mucous membrane of the bladder have two objections. The first is, that although by covering the exposed mucous membrane they preserve it from external circulation, they do not prevent the escape of urine. This escapes and soils the patient exactly as it did before the operation. The method which Maydl proposed, and the one which I have adopted in the present case, is to remove all of the exposed mucous membrane of the bladder except that which is immediately around the openings of the two ureters. After this has been done the abdomen is opened, the ureters are mobilized and the sigmoid flexure is drawn from the abdominal opening. A longitudinal incision is made into the intestine and the extremity of the ureters with their mucous covering is inserted into the sigmoid and made fast by a series of sutures. When this has been done the intestine is dropped backward into the abdominal cavity, and the abdominal cavity is closed. Up to the present time it seems to me that no method proposed gives as much relief as that used upon the patient whom I present to you to-day.

Dr. C. A. Wheaton, of St. Paul, read a paper by the same title. The doctor recited a case of hypospadias with rudimentary penis, a case of epispadias without exstrophy of the bladder, and a case of aggravated epispadias with exstrophy of the bladder, upon whom he had operated, Two patients were exhibited, showing satisfactory results.

The discussion on the two papers was opened by Dr. Rudolph Matas, of New Orleans. He thought that the surgical history of exstrophy of the bladder was a fair reflex or mirror of the progress accomplished in surgery, that the cure of ectopic vesicæ was a problem that had confronted and vexed the surgeon for nearly a century; the ancients simply referred to this condition and described it; to them it was a hopeless state. He pointed out that all the autoplastic methods proposed for the cure of exstrophy of the bladder are unsatisfactory and at best simply palliative; that of all the radical methods which involve an incision of the bladder and a transplantation of the ureters to the rectum, Maydl's operation is by far the most complete, rational and satisfactory from the technical point of view; that Maydl's operation offers the best conditions for the complete correction of the associate epispadias; that it should not be applied indiscriminately to all cases, but only to those patients whose general condition is such as to warrant a long, tedious operation likely to be attended by serious shock, and whose eliminating organs, especially the kidneys, are normal and capable of effective elimination.

Dr. DeForest Willard, of Philadelphia, Dr. J. Rilus Eastman, of Indianapolis, Dr. W. J. Means, of Columbus, O., and Dr. D. P. Allen, of Cleveland, joined in the discussion.

Dr. J. E. Moore, of Minneapolis, read a paper entitled

TUBERCULOSIS OF FASCIA.

He said that every surgeon was familiar with tuberculous fascia, secondary to disease of the glands, bones and joints, but in these cases the communicating sinuses are found, and the relation between the disease of the fascia and the gland, bone or joint is easily established. He said he had a history of a number of cases in which there was no disease of the gland, bone or joint, and in which there was extensive disease of the fascia. The symptoms of fascial tuberculosis are a slowly developing swelling, accompanied by little or no pus, and a local rise of temperature which can be detected by a sensitive hand. The diagnosis is to be made largely by exclusion. In the majority of cases the disease is secondary as well as primary. The prognosis varies with the variety, the location and extent of the disease. Treatment consists in thoroughly removing every trace of the disease with knife, curette and scissors. He gave the history of six cases.

In discussion, Dr. Willard, of Philadelphia, thought that Dr. Moore had struck the proper method of procedure in tuberculosis of the fascia, when there is no implication of the bone, by laying open the sinus.

Dr. Sherman, of San Francisco, spoke of the x-ray in connection with diagnosing conditions.

Drs. W. W. Keen and W. S. Jones contributed the next paper, which was entitled

TWO NOVEL CASES OF SURGERY OF THE TRACHEA: (1) STRICTURE OF THE TRACHEA SUCCESSFULLY REMOVED BY OPERATION; (2) SUCCESSFUL REMOVAL OF A DIAPHRAGM IN THE TRACHEA FOLLOWING CUT-THROAT AND PRODUCING APHONIA.[1]

In discussion, Dr. Crile, of Cleveland, thought Dr. Keen's case highly interesting, and reported a case of stenosis of the larynx under his observation.

Dr. Wyman, of Cleveland, said: I would like to know whether a more careful and painstaking suturing primarily of the case might not have averted the conditions that culminated in the operation by Dr. Keen?

Dr. Keen said: In reply to Dr. Wyman, I beg to say that I did not refer to the early treatment of this case simply because it was under the care of other surgeons. Dr. Jones and I never saw the case until more than a year after the cut-throat. I presume this little accident is quite as frequent in Philadelphia as in Michigan, and we try, in these cases, when we meet with them early, to repair the damage with immediate suture, as has been properly indicated by Dr. Wyman. In answer to Dr. Crile's question as to cicatricial stenosis, I should think that if the opening

[1] Philadelphia Medical Journal, p. 1,295.

between the vocal chords is completely cicatrized there would be no great probability of any progressive stenosis. If there were, it could be readily met by reintroduction of the tube.

DR. M. L. HARRIS, of Chicago, Ill., read a paper on

LONGITUDINAL SILVER-WIRE SUTURE IN THE CLOSURE OF WOUNDS.

I cannot speak too highly of the longitudinal silver-wire suture in the radical operation for hernia, as the results have been so gratifying. There are no absorbable sutures to soften nor no absorbable sutures to come out at some future time. Another advantage is its rigidity; it can always be sterilized; does not convey infection to the deeper tissues; edges of wounds are more coapted than by any other method; the narrow linear cicatrix is a great improvement in a cosmetic sense; the suture will withstand any desirable amount of traction without yielding; it is easily applied.

In discussion, DR. LORD said that he had discarded the deep silver-wire sutures, and that he was using silkworm-gut and catgut for superficial skin-wound closures.

DR. MEANS, of Columbus, mentioned a new material for suturing wounds — annealed steel wire, galvanized, and said it was very economical.

In answer to a question by DR. EGGLESTON, of Seattle, as to whether the silver wire was as easily removed as silkworm gut, DR. HARRIS replied that it was.

DR. J. C. MUNRO, of Boston, read a paper on

LAMINECTOMY, WITH REPORT OF CASES.

In discussion, DR. FERGUSON, of Chicago, said he thought that laminectomy was a very major procedure for the amount of good obtained.

DR. BOUFFLEUR, of Chicago, believed that shock was no contraindication to laminectomy; on the contrary it was a positive indication. He did not believe that presence of sensation accompanied by paralysis is a contraindication to operation. He said: The last case I had to recover, which was a year ago last September, was one in which sensation was present, but upon exposure of the cord we found a spicula of bone penetrating the cord and passing completely through it from behind, and doing a great deal of damage to the motor areas.

DR. FRANCIS D. PATTERSON cited a case of spinal meningitis, ameliorated by lumbar puncture.

DR. BAILY, of Chicago, said he had operated on two cases. One was an injury to the lumbar vertebra from a serious traumatism; the other was a gunshot wound; both were doomed.

DR. L. L. MCARTHUR, of Chicago, Ill., read a paper on

PANCREATIC CYSTS.

In discussion, DR. TURCK, of Chicago, reported a case of pancreatitis hemorrhagica associated with peripancreatitis in the clinic of the Post-graduate Medical School.

DR. FRENCH, of St. Louis, also reported a case.

DR. A. F. JONAS, of Omaha, Neb., read a paper on

RESECTION FOR THE CURE OF KNEE-JOINT TUBERCULOSIS, WITH A PLEA FOR EARLIER OPERATION.

He said that in the past ten years he had had 55 cases under his care, and that the methods of treatment employed came under these different heads: Mechanical immobilization, with plaster-of-Paris or starch bandage and braces; intra-articular injections of iodoform emulsion, followed by compression; puncture with canula and copious irrigation with sublimate solution; free incision and irrigation, with closure by suture without drainage and immobilization; para-articular operations, opening of abscesses, excavation of bone centres; arthrectomy; resection; amputation.

In discussion, DR. MOORE wanted to go on record as to the uselessness of iodoform in the local treatment of joint tuberculosis.

TREATMENT OF POPLITEAL ANEURISM BY EXCISION.

DR. J. C. OLIVER, of Cincinnati, O., read a paper under this title, reporting a case of traumatic aneurism of the popliteal artery in a syphilitic. He believes that the operation by extirpation is the most scientific of all methods thus far proposed for the treatment of aneurisms of the extremities; that it is by far the safest method; that it gives a greater percentage of cures and a less percentage of deaths than any other method; that the operation by extirpation should be resorted to without previous attempts to cure by any other method.

In the absence of DR. SOUCHON, DR. MANLY opened the discussion on the papers.

He was followed by DR. L. FREEMAN, of Denver, and DR. LORD, of Omaha.

THIRD DAY.

DR. A. F. HOUSE, of Cleveland, O., read a paper on

SURGICAL TREATMENT OF ACUTE PERITONITIS.

He believed that death from peritonitis was due rather to rapid intoxication than to inflammation. He recommended making exploratory incision in peritonitis. Early diagnosis is most important and operation should be performed just as soon as the diagnosis is made. The bacillus coli communis, derived from the intestinal tract, is the usual infection. Symptoms demanding immediate operation are general abdominal pain referred to the umbilicus, tenderness on pressure, early rigidity of the abdominal muscles, vomiting of a green substance, distention of the abdomen, pulse thready, weak and rapid, and diminished peristalsis. The operation should consist of three incisions, thorough irrigation of the peritoneum with normal salt solution and drainage by strips of gauze. If the intestines are greatly distended, they should be punctured or incised and their contents evacuated.

DR. A. J. OCHSNER, of Chicago, opened the discussion. He said: This paper of Dr. House's is certainly one of the most important subjects we have discussed during this meeting, and it should be discussed thoroughly. The danger from general septic peritonitis, from which patients die, I think is very analogous to the condition from which patients used to die when surgeons were in the habit of emptying a greatly distended septic bladder; the patient would die within forty-eight hours from what was supposed to be acute nephritis, but what in fact was a very acute sepsis. I am willing to say this — if the septic material in the intestine is stopped, if that patient is not treated medically, if he receives absolutely no medicine, and abso-

lutely nothing that will be found to make more microbes in the intestinal canal, that patient in almost every case will get well. I see dozens of these cases in this condition. I stop the feeding absolutely; I do not give them enough milk or gruel or broth to kill them, because that will increase the amount of septic material in the abdominal canal. If the patient has stercoraceous vomiting, I wash out the stomach. He receives rectal feeding.

DR. J. B. MURPHY, of Chicago, followed in discussion. He said, in part: The important factors I believe in peritonitis are, first, the diagnosis. When does a patient get a peritonitis? When does he get a general peritonitis? And can you recognize that he has a general peritonitis or a local peritonitis that is extending along and is going to become a general peritonitis? The important matter in connection with general peritonitis, as I look on it, is the type of infection. What is the character of the infection? What is the course of that type of infection after the peritoneal surface has been inoculated? We know from experience and opening the peritoneal cavity that contains a large quantity of pus that patients get well. We know from experience that cases with small quantity of pus opened and drained will be fatal; we know from experience that when we see a peritoneal cavity, when the peritoneum is not blistered, when the peritoneum retains its gloss, regardless of the quantity of pus, that the patient in a large majority of cases recovers; we know from experience when we open the peritoneal cavity, regardless of the quantity of pus, that patients with a blistered peritoneum — that is, where the intestine has lost its gloss — the cases will die. We must go back to the type of infection. I believe from cultures we have made from these cases that the blistered cases are of the streptococcus type; I believe again that a large quantity of pus cases are of some other kind — I speak of the pathologic condition when you open the peritoneal cavity. If the peritoneum is blistered, I do not recall a single case that has not been fatal. Where the peritoneum has not been blistered, many, many of them have recovered. I believe all cases of general peritonitis should be treated in the early stage. I believe the diagnosis should be made on pain, tenderness, nausea, vomiting, temperature, distention — and this is not an early symptom, it is the last of the symptoms; it may not be present; you should not wait for collapse or shock; collapse is practically a fatal condition.

DR. BRANHAM, of Baltimore, also joined in the discussion.

DR. MCRAE, of Atlanta, Ga., stated that he had collected, recently, statistics of 601 cases of septic peritonitis subjected to surgical intervention, with a mortality of 79 + per cent. They were all treated surgically, and these results are better than can be obtained by other measures.

DR. PORTER, of Fort Wayne, then took part in the discussion. *(To be continued.)*

AN EXAMPLE NOT TO BE FOLLOWED. — Dr. Klebs has opened in Chicago a private free dispensary for the poor, thereby introducing the German custom into this country. Certainly he deserves no thanks from the medical profession for this innovation, especially as we are just now seeking a remedy for the surplus of existing dispensaries in our cities. — *Cleveland Journal of Medicine*

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 13, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ANNUAL DISCOURSES AND ADDRESSES: AN EXPLANATION.

IT has been called to our attention that our editorial communication of June 22d on "The Shattuck Lecture and Annual Discourse at the Massachusetts Medical Society" might be construed as a reflection on certain other discourses which have gone before. Such an idea was furthest from our mind, as we think a careful perusal of the editorial in question would demonstrate. We must adhere still to our general proposition that the oration delivered at annual gatherings is apt to be merely retrospective and often complacent, and hence unstimulating. In making this statement we had no intention whatever of confining our generality to the Massachusetts Medical Society. Our experience has been that the shortcoming of which we speak extends much farther than the confines of Massachusetts or America. Nor, furthermore, did we intend to imply that there have not been notable exceptions to this general rule; it simply was not our intention to dwell upon other exceptions than those which this year's meeting of the State Society gave us, and which, being the last, are most prominently before our minds. We take it that both the Shattuck Lecturer and the author of the Annual Discourse would be the first to disclaim entire originality in the presentation of their themes, and we certainly had no intention of giving that impression in our remarks concerning them. A glance at the proceedings of our own Massachusetts Medical Society during the past few years would dispel such an idea at once.

These latest discourses had, however, in a pre-eminent degree what others, no doubt, have also frequently had, a spirit of dissatisfaction with the present and high hope for the future, which we maintain are the elements which constitute a stimulating oration.

We are doing no one injustice when we generalize in any matter whatever, and just as little do we do injustice when we particularize. In our editorial of June 22d we have generalized regarding the annual oration as it occurs the world over, and particular-

ized regarding the two discourses which graced the meeting of 1899 of the Massachusetts Medical Society. We have, therefore, reflected on no one.

THE FLOATING HOSPITAL.

THE Boston Floating Hospital, which for several years has done an excellent work in caring for infants during the hot summer months, will this year fill a more important place than ever before, owing to the lack of accommodation for sick infants in other institutions. The West End Nursery and Infants' Hospital has closed its doors for the summer to house patients, and the hospital on Rainsford's Island, which for a number of years has been a refuge for many babies, will not be opened this year. It is a perfectly well-recognized fact that the mortality among infants during the summer in large cities is very great, even if they have the care which a hospital affords. It therefore becomes imperatively necessary that provision should be made for their treatment outside the confines of the crowded portions of the city.

It appears that the managers of the Floating Hospital are making this year a special effort to meet the added demands which will no doubt be thrown upon them. Last year a worse enemy than disease to contend against proved to be humidity and weather conditions generally. Death resulted in a number of cases, which might have been avoided could the atmosphere have been kept dry and cool. The physicians in charge have therefore thought that could a ventilating plant be introduced, through which the temperature could be kept at a constant point, not rising above 70°, the efficiency of the hospital might be greatly increased. To this end an appeal has been made for $3,000, which we hope may be forthcoming.

As the hospital has developed, the need of more accommodation for permanent patients has been felt and this year a third ward is to be established for that purpose, increasing the capacity of the hospital by forty patients.

The plan of caring for sick infants by means of floating hospitals has so often demonstrated its usefulness, and our own has already done so much toward the alleviation of conditions met with among infants in summer, that we look with confidence toward its still further development.

SURGICAL INSTRUMENTS ADMITTED FREE OF DUTY.

A DECISION of great interest to the medical profession was made last week by Judge Colt, in the United States Circuit Court, in which he reversed the decision of the Board of General Appraisers, which assessed a duty of 35 per cent. *ad valorem* on an importation of surgical instruments made by the Massachusetts General Hospital.

A duty was assessed upon the instruments under paragraph 177 of the tariff act of August 27, 1894, which provides that "manufactured articles or wares, not specially provided for in this act, composed in whole or in part of any metal, and whether partly or wholly manufactured," should pay a duty of 35 per cent. *ad valorem*.

The hospital corporation contended, and the court held, that the surgical instruments which were imported for use in the hospital in its clinics and training school for nurses were entitled to entry duty free, under paragraph 585 of that act, as scientific instruments. The amount of the duty as assessed was $578.

The court said, "Looking at the whole of paragraph 585 and giving to it a construction in accordance with what seems to have been the intention of Congress, the term 'scientific instruments' means instruments specially designed for use in any particular science, and which are principally employed for such purpose; and, surgery being a science, it covers the surgical instruments in question in this case, which were imported for the use of the Massachusetts General Hospital in its clinics and training school. The fact that such instruments are employed by surgeons in the practice of their profession does not make them mechanical instruments.

"Instruments of this kind, in our opinion, are scientific instruments within the meaning of the statute until it is shown that their principal use is in the trades and arts. For example, an ordinary knife is a mechanical instrument, because its principal use is in the trades and arts, while a surgeon's knife, specially designed for use in surgery, and principally used for such purpose, is a scientific instrument."

The cost of carrying on the case was borne by a member of the medical profession, whose generosity in providing from his own resources for the costs of the case will result in no small benefit to hospitals and schools of medicine and surgery.

MEDICAL NOTES.

DR. MAZZONI THE POPE'S SURGEON. — Dr. Mazzoni, to whose intervention recently Pope Leo XIII owes his restoration to good health, has been appointed by the Pope to be his surgeon-in-chief.

UNIVERSITY OF VIENNA. — Dr. Emil Zuckerkandl, professor of anatomy, has been elected Dean of the Medical Faculty, in succession to Dr. Theodor Puschmann, professor of medical history, who has resigned, because of failing health.

YELLOW FEVER AT SANTIAGO. — It is reported that Gen. Leonard Wood, on his arrival at Santiago from the United States, found the situation more serious than he had anticipated. The headquarters were moved to Songo, twenty miles north, which is about one thousand feet above sea level. All the administrative departments, except the sanitary and a few immune clerks in the quartermaster's and commissary

staffs, were removed to that point. The paymaster has been ordered to suspend all payments to the Cuban troops until the fever has been stamped out, the special object of the order being to prevent the soldiers from drinking during the epidemic.

ANOTHER CASE OF TOTAL EXTIRPATION OF THE STOMACH. — Friday, June 9th, as we learn from the *Philadelphia Medical Journal*, Dr. Kocher, in his clinic at Berne, made a total extirpation of the stomach for carcinoma of the pylorus. The case was held to be favorable because of the absence of lymphatic involvement. The patient was a woman about forty years of age. The stomach was removed as a whole, including the cardia, and a direct anastomosis was made between esophagus and duodenum. The patient recovered from the operation, and apparently was doing well until June 13th, when, for some unaccountable reason, she died. At the post-mortem it was found that, in spite of the great care exercised not to interfere with the circulation of the intestines, the nutrition was sufficiently bad to cause a small area of necrosis in the wall of the transverse colon. As a result of this there was a mild peritonitis, which in the patient's poor condition was enough to cause death. The field of the operation itself was found in good order, the esophagoduodenal anastomosis having nearly healed.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 12, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 52, scarlet fever 25, measles 62, typhoid fever 16, small-pox 2.

FREE VACCINATION ENDED. — The free vaccination station in South Boston was stopped last week by the Board of Health, 1,256 persons having been vaccinated. This last free vaccination brought out the fact that many of the school children in the district had not been vaccinated, though this treatment is requisite for attendance at a public school.

NEW YORK.

THE STRAUSS MILK DEPOTS. — The Nathan Strauss milk depots have recently been opened for the season at various points in the down-town tenement districts, on the recreation piers, and in a number of the public parks. Pasteurized milk and raw milk freed from impurities by the centrifugal process, are sold by the glass (one-half pint for one cent), and pure and modified pasteurized milk furnished in bottles for infants at nominal rates, or free to mothers too poor to pay. There can be little doubt that the more or less general use of sterilized milk has been an important factor in the reduction of infant mortality in New York during the past few years, and it seems probable that the high death-rate among children under five years of age which has of late been noted in Brooklyn may be due, in part at least, to the fact of the less frequent employment of sterilized milk there than in the Boroughs of Manhattan and the Bronx.

THE FLOATING HOSPITAL. — On July 6th, the fifteenth anniversary of the first trip of its floating hospital, the St. John's Guild commenced its summer campaign of active work among the sick babies of the tenement districts. On that date the fine new hospital boat, the *Helen Juillard*, made its first regular trip down the bay, collecting its load of mothers and children from various landings on the east side of the city, while the old boat took its passengers from the west side. At the same time the enlarged seaside hospital of the Guild at New Dorp, Staten Island, was opened for the season. For the past six years there have been three floating hospital trips from both the east and west side every week, but during the present summer, with the increased facilities afforded by the new boat, there will be six weekly trips from each side.

PUBLIC MONEY FOR PRIVATE CHARITIES. — In response to a request from Controller Coler the Charity Organization Society, through a special committee, of which Robert W. De Forest is chairman, has given expression to its views regarding the appropriation of public funds for the support of private charities. The committee gave the matter a careful investigation, and its report is in part as follows: "The result has brought out the exceptional and unique position which New York occupies among all American cities in making large grants to private charities, and the equally striking unanimity of expert opinion against such grants. Of the twenty-nine large cities in the country other than New York included in our examination, twelve, or nearly half, make no grants whatsoever from public moneys to private institutions. Although there are exceptions, it may be said that the general principle governing the matter in the cities and towns of the United States is that public money is given only to public agencies." Having mentioned Washington, Baltimore and Richmond as among the exceptions, the report goes on to say: "In Chicago there are no appropriations corresponding to appropriations made to charitable institutions in New York City. In Boston there are no appropriations whatever to private charities. The same is true of Cincinnati, Cleveland and Pittsburgh, and many smaller cities. A large majority of the twenty or more persons with whom we have corresponded, and who may be regarded as authorities on the subject, emphatically oppose the policy of appropriating funds from the public treasury to private agencies."

MEASURES FOR LIMITING EXPENDITURE FOR CHARITIES. — The following are the recommendations made by the committee: Limiting present appropriations to such classes of agencies as children's institutions and hospitals; discontinuing appropriations to medical dispensaries, abolishing appropriations for fresh-air work carried on by private socie-

ties; continuing appropriations to industrial schools only until they are assimilated with the public-school system; that appropriations to foundling asylums and to children's institutions be upon a per-capita and per-diem basis, and that inmates be accepted by the Department of Charities in advance of payment by the city; that the aggregate amount contributed to hospitals be apportioned on a per-capita and per-diem basis for the patients, and to be divided proportionately to such service among all incorporated and well-managed institutions; no payment to be made for patients cared for in endowed beds. In conclusion, the report urges the necessity of regarding the present exorbitant amount appropriated to private charities as a maximum, and of effecting a very considerable decrease in the amount for each succeeding year.

A GIFT TO THE GERMAN HOSPITAL. — Mrs. C. Knaupp has contributed $10,000 towards the completion of the new German Hospital in Brooklyn, the gift being made on condition that should the donor ever meet with reverses and her condition necessitate her going to such an institution, she shall be received at the German Hospital and treated free of charge.

YELLOW FEVER AT QUARANTINE — TRIAL OF DR. DOTY'S SERUM. — Among the passengers who arrived on July 6th from Santiago on the United States transport *McClellan* were two yellow-fever patients, Oscar Lackey, of Philadelphia, and Miss Ellen Clendenin, a daughter of Dr. Paul Clendenin, the surgeon in charge of the Santiago hospital, who died of yellow fever after the *McClellan* had sailed. These, together with Miss Clendenin's sister and two fever suspects, were taken to the quarantine hospital on Swinburne Island, while the crew and other passengers were transferred to Hoffman Island for observation. In the case of Mr. Lackey, whose condition was serious, Dr. Doty decided, with the patient's consent, to make the first trial in the human subject of his new yellow-fever serum. At 11 P. M. an injection of 25 cubic centimetres was made, and three and eight hours afterwards a second and third injection, each larger than the preceding, were given, the total quantity of serum employed being 90 cubic centimetres. Apparently as the result of the remedy, there ensued a marked decline in temperature and relief of gastric irritation, while the general condition of the patient so far improved as to afford a hope of his making a good recovery.

DIPHTHERIA AT A HOSPITAL FOR THE INSANE. — The Willard State Hospital for the Insane has been placed under quarantine on account of an outbreak of diphtheria. A considerable number of both inmates and employees have been attacked, but the disease is stated to have been of rather a mild type and antitoxin has been freely employed.

SUTURE OF THE HEART. — A case is reported from Binghamton, N. Y., of stab-wound of the heart penetrating nearly through the walls of the left ventricle, in which Dr. F. L. Forker, of that place, after administering a saline intravenous injection to offset the loss of blood that had occurred, sutured the injured organ. The patient survived for forty hours, when death resulted from septic pericarditis.

A WIDOW'S RIGHT TO HER HUSBAND'S BODY. — On June 29th Justice Bischoff, in the Supreme Court, handed down a decision respecting a widow's right in the body of her husband. The case was that of Mrs. Mary Buchanan et al. *vs.* James D. Buchanan, an action for replevin and damages in the amount of $5,000. The plaintiff is the widow of Dr. Alexander Buchanan, who died September 2, 1896. The body was interred in Greenwood Cemetery by the brother of the deceased, James D. Buchanan. Mrs. Buchanan was not consulted as to the disposition of the remains, not having lived with her husband for nine years previous to his death, and having an action for divorce against him pending in the courts at the time of his death. A year after his death she brought the action for the possession of the body and damages for its unlawful detention. In the trial of the case, in which a jury was dispensed with by consent, the evidence introduced and uncontradicted was to the effect that just before his death Dr. Buchanan extracted a solemn promise from his brother, before a number of witnesses, that he would never allow his ashes to mingle with those of his wife. In his opinion the judge said that while it had been generally stated that there could be no right of property in a dead body, still it was recognized that there exists a personal right in husband, wife or next of kin to have the custody of the remains of the deceased relative for the purpose of burial. In this case, however, there was no question that husband and wife were divided in life, and it was the expressed wish of the deceased that they be as fully divided in death. Judgment was, therefore, ordered for the defendant on the pleadings.

ARMY NOTES.

APPOINTMENTS OF HOSPITAL STEWARDS IN THE NEW VOLUNTEER REGIMENTS. — General orders establishing the new regiments of volunteers provide that candidates for appointment as hospital steward, must produce certificates of proficiency from a reputable college of pharmacy, and after enlistment will be appointed as such by the colonel of the regiment upon the recommendation of the surgeon of the regiment, the warrant to be made, and the appointment to take effect, on the date of enlistment. Army regulations applying to hospital stewards in the regular army, except as herein otherwise provided, will apply to regimental hospital stewards who may be discharged from the service, for cause, by the Secretary of War, upon the recommendation of a board of three officers convened by the regimental commander to investigate and report upon the case.

GENERAL WOOD'S JURISDICTION EXTENDED. — Gen. Leonard Wood, who recently sailed for Santiago, has been appointed military governor of the prov-

ince of Porto Principe in addition to that of Santiago, thus being placed in control of about half the island of Cuba.

DEATH OF DR. CLENDENIN FROM YELLOW FEVER. — The second medical officer to succumb to yellow fever at Santiago was Capt. Paul Clendenin, assistant surgeon, U. S. Army, who was in command of the general hospital at that place. Dr. Clendenin was the son of Gen. David R. Clendenin, U. S. Army, and was thirty-seven years of age, having been in the military service for thirteen years. Immediately prior to the outbreak of the war with Spain he was on duty at Key West, and was sent from that point to Havana to attend the victims of the *Maine* at the first news of that disaster. Dr. Clendenin was twice married, and leaves several children; one daughter, who left Santiago several days previous to his death, experiencing an attack of yellow fever while on board the transport *en route* to New York.

MEDICAL APPOINTMENTS TO THE NEW VOLUNTEER REGIMENTS. — The President has appointed the following medical officers to serve with the eight regiments of volunteer infantry, recently created for service in the Philippines, a major, captain and lieutenant being assigned to each regiment. The appointments, together with the former service of the appointees, are as follow: Surgeons, with the rank of major, — Ogden Rafferty, captain and assistant surgeon, U. S. Army, late brigade surgeon, volunteers; Charles F. Watson, captain and assistant surgeon, U. S. Army, late brigade surgeon, volunteers; John R. McDill, late brigade surgeon, volunteers, now acting assistant surgeon U. S. Army; Frank C. Armstrong, late surgeon, 21st Kansas Volunteers; Thomas W. Chalmers, late surgeon, 12th New York Volunteers; Charles L. G. Anderson, late assistant surgeon, U. S. Army, now acting assistant surgeon, U. S. Army; B. Albert Lieberman, late surgeon, 6th Missouri Volunteers; Joseph N. Henry, late surgeon, 4th U. S. Volunteer Infantry. Assistant Surgeons, with the rank of captain, — John R. Hereford, late surgeon, 1st Missouri Volunteers; James C. Minor, late surgeon, 1st Arkansas Volunteers; Frank W. Foxworthy, late assistant surgeon, 160th Indiana Volunteers; Abram L. Haines, late surgeon, 203d New York Volunteers; James J. Erwin, late assistant surgeon, 10th Ohio Volunteers; W. E. Parker, late acting assistant surgeon, U. S. Army; James E. Shellenberger, late surgeon, 3d Ohio Volunteers. Assistant surgeons, with the rank of first lieutenant, — William H. Cook, acting assistant surgeon, U. S. Army; Lomax S. Anderson, late assistant surgeon, 5th U. S. Volunteer Infantry; Leonard K. Graves, late assistant surgeon, 201st New York Volunteers; Ralph S. Porter, late assistant surgeon, 2d Illinois Volunteers; John A. Metzger, acting assistant surgeon, U. S. Army; Patrick J. McKenna, late assistant surgeon, 2d U. S. Volunteer Engineers; Albert H. Eber, late assistant surgeon, 35th Michigan Volunteers; John E. Boyd, late captain, 2d South Carolina Volunteers.

Correspondence.

CALVIN ELLIS.

MR. EDITOR: —

To one who recalls the character of our dead friend it seems like a derogation to feel so much of gratulation, and to speak so much of eulogy, because of his large bequest of *money* to the cause of medical education. Is it unknown, or is it quite ignored, that the legacy in which he felt the highest pride was that of the faithful record of his professional work bequeathed to those who may come after him? It may be dry and faded like the herbarium of a botanist, but it is a *thesaurus* of classical labors collected during many years of conscientious and thorough study. We know that in every page will be found careful observation and honest registration by a competent man, and that such work is at least as worthy of preservation, as valuable to posterity, as that which describes plants, their forms, growth, flowers, etc. Will any one say that these things have no practical or scientific value? In the letters of our greatest American botanist, Dr. Asa Gray, we see how great importance he attaches to the study of the older botanists and of their herbaria, however dry or incomplete.

Is it not quite proper, indeed usual, in the disposal of a legacy of money, to use it, or a portion of it, in accordance with the known wishes of the testator, even when the will itself fails to indicate any such specific intention on his part? Now, it is well known to many of his friends that Dr. Ellis during his last sickness often regretted that his notes had not been transcribed, so that they might be published.

Why should not this be done now, and by the aid of a part of the income of his legacy?

His manuscript is not likely to prove at all as difficult as that of the cipher of "Pepys' Diary," which after two hundred years has been written into perfect form by the Rev. Mynors Bright, A.M., and under no finer stimulus than: "you may as well decipher afresh 'Pepys' Diary.'"

A far higher motive exists for deciphering the records of the professional life of Calvin Ellis.

Z. B. ADAMS, M.D.

METEOROLOGICAL RECORD

For the week ending July 1st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,406; under five years of age 1,034; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 475, diarrheal diseases 367, consumption 237, acute lung diseases 203, diphtheria and croup 53, typhoid fever 16, cerebro-spinal meningitis 16, measles 11, whooping-cough 10, erysipelas 2, small-pox 1.

From cerebro-spinal meningitis New York 5, Baltimore 3, Washington and Worcester 2 each, Boston, Cincinnati, Springfield and Everett 1 each. From measles New York 8, Boston, Baltimore and Lynn 1 each. From whooping-cough New York 9, Baltimore 1. From erysipelas Boston and Cambridge 1 each. From small-pox Boston 1.

In the thirty-three greater towns of England and Wales with an estimated population of 11,404,408, for the week ending June 24th, the death-rate was 16.3. Deaths reported 3,558; acute diseases of the respiratory organs (London) 190, measles 131, whooping-cough 90, diphtheria 80, diarrhea 58, fever 32, scarlet fever 18, small-pox (Hull) 1.

The death-rates ranged from 8.2 in Croydon to 22.9 in Wolverhampton; Birmingham 16.8, Bradford 14.8, Gateshead 17.6, Huddersfield 16.1, Leeds 15.9, Liverpool 21.9, London 15.5, Manchester 21.0, Newcastle-on-Tyne 18.3, Nottingham 16.8, Portsmouth 14.2, Salford 17.4, Sheffield 19.2, Swansea 15.1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 8, 1899.

RALPH W. PLUMMER, assistant surgeon, appointed surgeon from June 17, 1899.

J. C. WISE, medical inspector, granted sick leave for three months.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 6, 1899.

MURRAY, R. D., surgeon. To defer departure to Key West, Fla. (as directed by Bureau letter of May 16, 1899), until further orders, and to proceed to New Orleans, La., for special temporary duty. July 1, 1899.

WASDIN, EUGENE, surgeon. To proceed to Norfolk, Va., and assume temporary charge of the Service at that port not later than July 17, 1899. July 5, 1899.

MCADAM, W. B., assistant surgeon. Bureau letter of May 15, 1899, relieving Assistant Surgeon McAdam from duty at Key West, Fla., revoked and directed to reassume command of the Service at Key West. June 30, 1899.

ROBINSON, D. E., assistant surgeon. Relieved from duty at Chicago, Ill., and directed to proceed to Mobile, Ala., and report to the commanding officer for duty and assignment to quarters. June 30, 1899.

ALTREE, G. H., acting assistant surgeon. Granted leave of absence for four days. July 3, 1899.

BEAN, L. C., acting assistant surgeon. Granted leave of absence for two days. July 5, 1899.

APPOINTMENT.

MCISAAC, FRED C., appointed acting assistant surgeon, for duty at Evansville, Ind. July 3, 1899.

RESIGNATION.

BRUNNER, W. F., sanitary inspector. Resignation accepted as tendered, to take effect June 30, 1899. July 3, 1899.

RECENT DEATHS.

WILLIAM HOWARD NEILSON, M.D., a prominent physician of New Rochelle, N. Y., died on July 6th, after an operation for appendicitis. He was born in New Brunswick, N. J., in 1858, and was graduated from Bellevue Hospital Medical College in 1877. At the time of his death he was a member of the Westchester County Medical Society and of the Board of Aldermen of the city of New Rochelle.

J. E. GRAHAM, M.D., of Toronto, Can., who died a few days ago, was one of the most widely-known physicians of Canada. He was President of the Dominion Medical Association in 1887, of the American Dermatology Association in 1889, and was one of the original members of the Association of American Physicians. In 1893 he was made a member of the Royal College of Physicians, London.

BOOKS AND PAMPHLETS RECEIVED.

Die Ursache übler Nebenwirkungen heisser Bäder und deren Verhüting. Von Dr. Foss, dirigirendem Arzt des Bades Driburg in Westfalen. 1899.

A Ring-pleximeter. A Finger Protector for Handling the Headmirror. A New Hearing Device. By Emil Amberg, M.D., Detroit, Mich. Reprints.

On the Use of the Valerianates of Creosote and Guaiacol in the Treatment of Pulmonary Tuberculosis. By A. B. Briggs, M.D., Ashaway, R. I. Reprint. 1899.

Naphthalin in Typhoid Fever, a Remedy in Preventing Intestinal Putrefaction and Tympanites. By Albert Woldert, Ph.G., M.D., Philadelphia, Pa. Reprint. 1899.

Studies from the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York. Vol. VI, for the Collegiate Year 1898-1899. Reprints.

The Schleich Method of General Anesthesia, with Special Reference to Nose, Throat and Ear Practice. By W. Scheppegrell, A.M., M.D., New Orleans, La. Reprint. 1899.

The Influence of the Heart-beat on the Flow of Blood through the Walls of the Heart. The Teaching of Physiology in Medical Schools. By W. T. Porter, M.D., Boston. Reprints. 1898.

Urinary Analysis and Diagnosis by Microscopical and Chemical Examination. By Louis Heitzmann, M.D., New York. With 108 original illustrations. New York: William Wood & Co. 1899.

The Surgery of the Head and Neck. By Levi Cooper Lane, A.M., M.D. (Berol.), M.R.C.S. Eng., LL.D., Professor of Surgery in Cooper Medical College, San Francisco. Second edition. Philadelphia: P. Blakiston, Son & Co. 1898.

The Higher the Order of Railway Surgery, the Greater the Protection to the Employe, the Passenger and the Company. Appendicitis: When to and when not to Operate. By R. Harvey Reed, M.D., Rock Springs, Wyo. Reprints. 1899.

Text-book of Anatomy, Physiology and Hygiene. By E. Franklin Smith, M.D., Lecturer on Anatomy, Physiology and Hygiene, New York Preparatory School; Member of the New York Academy of Medicine, etc. New York: William R. Jenkins. 1899.

Anæmia and Some of the Diseases of the Blood-forming Organs and Ductless Glands. By Byron Bramwell, M.D., F.R.C.P.(Ed.), F.R.S.(Ed.), Physician to the Royal Infirmary, Edinburgh; Lecturer on the Principles and Practice of Medicine, and on Clinical Medicine in the School of the Royal Colleges, Edinburgh, etc. Edinburgh: Oliver & Boyd. London: Simpkin, Marshall & Co., Ltd. 1899.

Address.

NOT THE DISEASE ONLY, BUT ALSO THE MAN.[1]

THE SHATTUCK LECTURE.

BY JAMES J. PUTNAM, M. D., BOSTON.

MR. PRESIDENT AND MEMBERS OF THE MASSACHUSETTS MEDICAL SOCIETY: — I take as the text for my address the familiar sentiment that often falls so solemnly from the lips of older members of the profession in addresses to students who are about to graduate from the schools of science into the school of life: Remember, when you go to see your patients, that it is after all the man, not the disease, that you are called upon to treat.

Impressive as this phrase sounds, I have often wondered just what the various speakers had in mind. This patient might be poor in purse, that one predisposed to certain ailments; the social or domestic surroundings of a third might make his case a peculiar one, and so on. But such external circumstances, important as they might be, would not exhaust the significance of the admonition. We cannot really know the man whom we are called upon to treat without going far beyond his outward relations and penetrating in imagination deep into his mental life. "The man" is, above all else, the mind of the man, and not only the mind as an organ of conscious thought but the mind as an organ of bodily nutrition, and the mind as a vast theatre for the interplay of contending forces that do not always recognize the personal consciousness as their ruler. This is the man that the doctor should learn to know and treat. The need is not met by kindliness and humanity alone; the task is one for science also. Yet medical schools do not prepare their students at all adequately for this duty, or include a knowledge of psychology among their requirements for matriculation. The genius of the truly great physician may bring him to the goal, it is true, without a master's guidance. But if we are not content with the intuitions of the few; if we wish to see principles laid down that shall reflect the highest possibilities of medicine, the training of the doctor must begin during college life. I should rate a thorough preliminary course in psychology and philosophy far above a knowledge of botany or zoölogy, and as following close on chemistry and physics, as a preparation for the work of a general practitioner.

It is not the least of the benefits that will come to us from the insistence on a college degree as a condition for entrance to the Harvard Medical School, that a better chance will have been afforded for remedying this lack in the students' fitting. We want to see in the men whom our university sends forth, proud of her warrant of tasks faithfully performed, not only sporadic signs of a capacity to recognize and control, each after his own fashion, the gigantic and ever active forces of the mind, but abundant evidence that this problem has been, in all its many aspects, an object of their studious thought. The physicians who have previously been good students of psychology have, in my experience, proved themselves to be men of unusually broad sympathies and high ideals, and keen to see causes of disease to which the pure pathologist is often blind. For what a man sees or fails to see depends, as we all know, on how the vast storehouse[2] of his mind has previously been stocked. The inhabitants of that hidden world, like groups of men in society, welcome the new comer whose manner and dress are familiar, and let the others pass unnoticed.

No argument is needed to show what transforming power the mind can exert. The energy set free by the magic agencies of hope, courage, desperation, fanaticism, or by the enthusiasm for a great cause, may reveal the possession of a force undreamed of, or so husband the resources of the body as to keep the flame of life burning for a time when the oil seems exhausted. These great influences have been the doctor's best ally since time began; the harp of David singing to Saul is heard again in the music which is used to tie with new bonds to life the inmates of our State Hospital for the Insane at Danvers. The great leaders of the scientific centuries to which we belong have indeed turned a cold shoulder on the time-honored methods of cure by faith and fear which had worked miracles for ages past. Their work lay in establishing the reign of exact methods of inquiry, and they would tolerate no systems that rested on a less firm basis. But the movement which the labors of these men of science inaugurated is now secure beyond all hazard, and the time has come to recognize that there are others that may justly lay claim to our attention. We may accept the limitations which the scientific method imposes, even to the point of sacrificing intuition for the sake of a more conscious insight. But we should not admit any arbitrary limitation of the field of inquiry, nor rest content until scientific research has taken all the divinations of instinct into account. The splendid wave of pathological and bacteriological research that has raised the art and science of medicine to its present position of authority has set physicians trying to solve their problems in terms of pathology alone; but it is a matter for congratulation that this wave is being reinforced by another which is sweeping us toward a better knowledge of the secrets of the mental life in health and disease. Perhaps we may even learn thereby to interpret the teaching of pathology itself in a wider sense.

The physician is an educator; the successes of the schoolmaster are his successes; the fact that even

[1] Delivered before the Massachusetts Medical Society, June 13, 1899.

NOTE. — While this lecture is in press the news arrives — to the disappointment and grief of his many friends — of the fatal ending of Dr. Russell Sturgis's long illness. The loss is an especially serious one for the progress, in our community, of the cause which this address was designed to make more popular, and to the furtherance of which he had brought original investigations of substantial value.

[2] I do not think it really accurate to speak of the brain as a "storehouse," as is so often done, though the term is familiar and expressive. In fact, the brain is no more a storehouse of the events that have transpired in and through it than the brass disc is a storehouse on which the sand will shortly arrange itself, at the touch of the bow, in the wonderful Lissajou's lines, or than the sounding-board of a piano is a storehouse. When the brain is inactive (if one could imagine such a state) it is incapable of telling any story as to its history. But each new stimulus revives each old activity, of identical, or similar, or congruous, or contrasting sort, and so on. The reviving flash of consciousness which occupies each new moment, like the thrill which at the same moment sets the brain into vibration, is a single complex impulse, an instantaneous photograph, and although it takes the form of memory, it belongs in fact wholly to the present.

Neither does it seem to me exact, at least from the point of view of the cerebral physiologist, to speak of "inheriting ancestral experience." What we inherit is a brain so plastic in certain directions and so little inhibited on those lines that it organizes its experiences of certain sorts with great rapidity.

The power which passes as "intuition," and which seems endowed with faculties that transcend and antedate experience, may, I think, be, after all, experience — taught, though the teaching is marvellously rapid and effective. Any one of us, if he could have appreciated and appropriated and made his own all the opportunities that have been afforded him for education of the brain in any special line would be a genius in that direction.

after such long years of scrutiny and experience the pedagogue still finds new methods of impressing his pupils, and new principles to guide him, gives warrant for the hope that the same may prove true for the physician, provided only that he brings the same amount of patient labor to the solution of his special problems. I doubt if most general practitioners are aware how far, in fact, this hope is already realized. We all hear of the triumphs of surgery, and every doctor feels a personal pride in spreading the news of them abroad. But there are not so many who know that there are men, as yet few in number but of equal genius, who with equal devotion and study have been searching for means to change, little by little, the trend of the forces that work within the mind, and are thus silently laying the foundations of a new departure in therapeutics. This is education of a high order,[1] and such studies as these must yield conclusions that the well-trained doctor will find use for in his daily practice.

In the sort of training that is undertaken for the sake of breaking up morbid habits of the nervous system, or of establishing favorable habits under difficult circumstances, the need is even more evident than where only the teaching of the schoolroom is at stake — of inducing reactions that shall have an effective outcome. Definite accomplishment, and motion at any rate are often the prime conditions of mental health. If water does not flow it stagnates, and the more so in proportion to its lack of purity. To this outcome of effectiveness, the effectiveness which implies continuous growth through utilization of evil and of good, the influence of the doctor, above all other educators, is instinctively pledged. No wonder that his efforts are often crowned by disappointment and failure; these are but the disappointments and failures of the schoolroom intensified.

Fortunately, no one here is likely to interpret too narrowly the meaning of effectiveness. There is absolutely no criterion of accomplishment except that which should say whether or not a man had done his best. To refrain from acting is often the fullest act. Washington coolly facing his enemy and his own limitations, and waiting for the chances that rarely came, presents no figure of greater energy or heroism than is presented by the resigned, the cheerful, the ever-ready neurasthenic patient who is doing the best he can. "They also serve who only stand and wait."

The doctor is most obviously an educator in dealing with the training of children, when the task that he sets for himself is practically identical with that necessarily set for the schoolmaster and the parent. I refer to this class of cases for the sake of calling attention to the remarkable results now attained at the various institutions for defective children in this country and in Europe, among which our Massachusetts School for the Feeble-minded, under the able leadership of its present superintendent, might compete for the highest rank. So fine are the chances thus presented that the definition of feeble-mindedness is now being widened to secure the benefits of this training for children not heretofore recognized as defective. Even when regarded simply as schools for the training of teachers and the development of methods of teaching, such institutions as this are bound to hold an exceptional place, because in order that any success at all should be gained, the slightest action and reaction of each pupil's mind have to be recognized, while the educational principles that are followed must be of the best sort, and must be administered with personal devotion and close attention to details.

Even where the child is not strictly defective, but simply a hard case for the parent and the schoolmaster, the methods of influence to which clinical research has given birth are likely to find an important if not a wide field of usefulness. The subject is too large a one to speak of in detail, but there are cases, as the teacher should realize, where the birch and the fool's cap are less useful than the training by the aid of influences such as I shall presently refer to, to be administered under the skilled supervision of the doctor alone. Certain disorders of the physiological reflexes, such as enuresis, are eminent examples of an analogous though a more obviously medical sort. There are cases of this kind where even hypnotic suggestion, of a mild degree and such any physician can soon learn to use with safety and sufficient skill, is the best cure. In fact, the only rational treatment of enuresis and constipation consists in a re-training of the physiological reflex, and the re-establishment of the all-powerful habit and expectation on which they rest. Mechanical and medical means may be used to further this design, but the routine employment of drugs without this end in view does but rivet afresh the assumption and habit of failure. That part of the conscious life to which, after the early years of childhood, the control of such functions as these is delegated should be taught again to work in harmony with the general needs.

But the doctor is seen also in his function of educator when dealing with clinical cases of a commoner sort. Sometimes a process of training must begin afresh because the old machinery of the nervous system has become defective through disease. No year now passes without its records of new successes in this line.

Thus, in spite of all the study that has been given to the treatment of locomotor ataxia, it is only recently that we have learned (under the leadership of Frenkel) that patients with this disease, even when bed-ridden from inco-ordination, can be taught by systematic gymnastics to use their muscles anew, and can thus regain to a considerable degree the lost control over their limbs. A therapeutic discovery like this is a sign of promise, and an inspiration to new research in other lines. The ataxia of the muscles typifies also the ataxia of the mind and of the other functions of the nervous system. We pay dearly for the possession of the intricate machinery which gives us our vivid imagination, our retentive memory, and that power by which we are able to grasp at each moment all the threads of our past experience and to weave them into a new fabric for the service of the present. Mischief begins when the demands of this service cannot be properly met, and the different parts of the vast machine run too fast or too slow; the delicate adjustments fail to respond or work too fine. Then the heart palpitates, which should simply strengthen its

[1] I will refer, simply by way of illustration, to the recent searching analysis of clinical cases by the now well-known Pierre Janet: Névroses et Idées fixes, Paris, 1898. The following paragraph, p. 406, which concludes one of the chapters, may give some notion of the author's aim and spirit: "Objective psychology (that is, by clinical observation) does not aim at supplanting subjective psychology, which will remain indispensable for the study of the laws of thought. Neither does it aspire to set up any system of metaphysics or religion, or to overthrow any earnest belief. Its task is to gather together the facts which are essential for a real insight into the working of men's minds, and to discover the art of securing the freest play for healthy mental life and the best alleviation for mental disease."

beat to meet a need for more blood. Then a bronchitis provokes an asthma, and this recurs and becomes a habit. Or a painful impression that should have disappeared with its cause, swept down the swiftly flowing stream of consciousness, is caught by a backwater, or rolled to and fro in an eddy from which it cannot escape. Or, again, the instinct of imitation, imitation of others or of ourselves, makes us copy and perpetuate a bad trick of muscle or of thought. And so arise the diseases of morbid association and habit[4] the caricatures of the arrangements and co-ordinations of health. Here is a singer[5] who in the first days of his career found himself with beating heart[6] and shaking voice in consequence of a stage fright. He is now a veteran, and no longer stirred by fear of failure, yet his old fright remains indelibly stamped upon his trembling muscles, which do their best, in their turn, to drag back the old emotion. There is at first a divorce between the bodily manifestation and the mental state, and then a new union an abnormal lines.

"I am not frightened, but my body is," said an intelligent friend. "It is my body trembles at the sight of the dangers into which my triumphant soul will carry it," said a hero of an earlier day.

Or, again, to take an example of a habit disease of another sort, here is a patient who has had an inflamed joint. It is long since the local disorder passed away, yet the pains which used to attend it recur at every trifling movement which even remotely resembles those that used to drag upon the sensitive part. The demoralization following illness, or misfortune, or accidents, is a rich source of such disorders. A patient has haunted our hospital clinic for a long time who thirty years or more ago received a blow upon the head which set up a spectral pain that has been his constant companion ever since, though even now he looks in blooming health. Any innate weakness which prevents the brain from carrying on its normal function of prompt, efficient reaction may allow morbid tendencies of these sorts to establish themselves, as weeds grow in a soil too poor to support a better product.

It is not correct to say that these pains are "imaginary." Regarded psychologically, they are just like all other pains. On the field of battle even the ordinary physical causes of pain may fail to cause it, for the impression is followed by no reverberation within the soldier's conscious attention. In the conscious attention of the over-sensitive patient, on the other hand, this reverberation is excessive, and thus the merest hint of physical cause, a whisper of apprehension, the influence of cyclic recurrence like that which reproduces sleep, or even the influence of memory, may make the pain come back.[7]

Fortunately, the knowledge that so many of our ills have this mental origin stimulates to the search for new means of cure, for new means of securing some strong outward trend for the active forces of the brain and thus inducing a little of the healthy anæsthesia of the battle-field.

The patient finds it hard to credit the fact that his sufferings are due to mental representation alone, and no wonder. For by what criterion can he, unskilled and anxious, be expected to decide, when the physician, with all his means of diagnosis, is so often in doubt? Frequently, of course, the symptoms are only partly due to habit, and partly also to some local cause. Every good physician is aware of this, but it is not so well known that the removal of other physical disorders, perhaps not originally connected with the symptoms at all, but now a real complication, may induce a partial or temporary alleviation, which will supply the very impulse that was needed to give new hope to the mind and a new "set" to the functions of the nervous system. Thus it is that the treatment of trivial diseases of the eyes or joints can sometimes work such wonders; and thus, too, the new doctor so often eclipses the old. On the other hand, the keen physician will not let himself be trapped into the error of concluding that he has found the cause of the illness because he has found the cure. This is a piece of false reasoning that has worked much mischief and has often brought an unmerited credit to immature theories of disease.

The subject of the *social etiology* of "habit" disease has many interesting and important aspects. Prof. William James[8] has recently suggested that many of the racial peculiarities, such as the high-pitched, anxious voices, the hurried manner, the "over-modelled" faces that do not easily relax, the tense and exhausting eagerness, which visitors see so often among the people of old New England, are due not so much to excess of sunlight and dry air as to tradition and imitation. A comparative study of the varied races of which the population of New England is now composed, made from this point of view and as a basis for more rational treatment, would be heartily welcome. This or that American or Irishman or Jew cannot be treated to the best advantage so long as he is regarded solely as an individual. His racial traditions and temperament should be taken instinctively into account, just as the pianist (to borrow a simile used by Kries) on starting to play a piece of music, glances once for all at the signature which indicates the key in which the piece is written, and then, without need of specific reflection, goes on throughout playing the notes with their appropriate sharps and flats.

To learn to do this sort of thing, to speak and comprehend the mental language of all sorts and conditions of men, is one of the many important tasks which the physician will in time learn to perform.

The existence of these habit diseases is known to every doctor, but this very fact is liable to give one a false sense of confidence in his ability to recognise them. Common as we may think them, they are yet commoner than we think. The most striking forms are seen in hysteria, the chief characteristic of which is that the patient's consciousness is split up into more or less separate groups of forces, which strive

[4] At the last annual meeting of this Society various types of habit neuro-psychosis were described by Dr. Edward Wyllys Taylor: Boston Medical and Surgical Journal, July 21, 1898.

[5] This illustration is given by Dr. Morton Prince, and I take occasion, in citing it, to call attention to the excellent work which he has done in this direction. See various papers published in the Boston Medical and Surgical Journal, 1898; also Association Neuroses, New York Journal of Nervous and Mental Diseases, 1891.

[6] The presence of these cardiac and circulatory phenomena, as a part of the habit neurosis, is a complication of a peculiarly distressing and important sort ("Angst-neurosis"). See Heart Fear, by W. T. English: Medical News, April 29, 1899; also L'Education de la Volonté: Payot.

[7] Dr. Morton Prince has suggested that the excessive tendency to the mental representation of pain shown by certain persons justifies the designation of them as "algesics," just as other persons to whom visual images readily occur are called "visuals," and so on.

Dr. Mary Putnam Jacobi thinks it possible that the increased sensitiveness of the "pain-memory" may be a part of the general increased attention to the history of the past, though a morbid example of this tendency. New York Medical Journal, April, 1898.

[8] Talks to Teachers. 1899.

with each other for the mastery. The patient is no longer a consistent unit, and is forced, against his will, to play, with the skill of genius, the rôle of disease.

But hysteria is not the only soil on which these disorders grow, unless indeed we admit that the hysterical tendency is universal, and that hysterical disabilities and eccentricities are but acute forms and caricatures of the disabilities of normal or quasi-normal life. The term "hysteroid," which retains the notion that such affections are due largely to mental representation, is often an appropriate designation.

The "accident neuroses" form an especially important sub-group, the more so that one can trace, both in the influences which make certain classes of patients peculiarly susceptible to them, and in those which finally excite the outbreak and give it its special form, the play of forces that recall "hypnotic suggestion," and are seen at work on a large scale in mob-madness or panic. The patients who suffer from the severer forms of these disorders are, strangely enough, largely of the mechanic and wage-earning class, who, although sturdy, and used to hardship of various sorts, are apt to be lacking in social and general experience, and are not trained in the sort of self-control that society expects from its members, while, at the same time, their lack of a fixed source of income makes a period of enforced idleness a matter of great moment to them. They are not, as a rule, predisposed by neurotic inheritance, and have usually been strong and healthy, but the traditions of the community in which they were born and bred inculcate the instinctive belief that accidents are terrible events and lead to mysterious and complex troubles. To the patient whose mind is thus stocked with traditions and instincts sympathetic to misfortune, there come next the startling and disabling circumstances of the accident itself, which dethrone the self-control and profoundly disturb the emotions and through them the action of the circulation and the heart, and to this is added the special "suggestion" furnished by some local injury or special fear. It is then as if some one had whispered to the demoralized patient, "Your arm will be paralyzed," or, "You will be an invalid for years." These cases are extremely numerous and immense sums are paid on them in damages. The general practitioner can do the community great service by recognizing and spreading the view that serious as such illnesses often are it is largely mental causes that make them so. A stalwart position of hopefulness taken by the attending physician, at the outset, as a basis for a persistent and thorough treatment by encouragement, and explanation, and personal influence, before morbid habits and invalidism have become ingrained, may save many a patient from a demoralization that the money secured by the verdict cannot make good. How often, on the other hand, does the doctor say: "Madam, you really ought to take care of yourself; you are far more severely injured than you think you are." There is usually a period, to be sure, at the very beginning of the case, when it could be said with truth that the patient is "more severely injured than he thinks he is," because the disturbance that is going on in the deep sea of his mental life has not yet reached the surface. But for him this is a blessed ignorance, and it is a misfortune when the time comes that it is exchanged for a delusion as to the real nature of his disease. It is not the hope of gain that is the prominent factor here, in spite of the raillery of the court room. Doubtless it plays its part, but the essential influence is the disorganition of the forces that rule within the mind, and that, instead of acting in harmony, as they should, break into disorder, like soldiers in panic, and then instinctively seek to readjust themselves under any tolerable, if imperfect, organization and leadership. Happy it is for the patient if this reorganization is effected under the guidance of a doctor who has had the fortune to be graduated with high marks from some philosophical department as admirable as that of our good foster-mother across the river, and thus buoyed up, has brought an undivided will to the study of medicine.

In the treatment of all these "habit" cases, a persistent and insistent *encouragement*, based on a physical examination of rigid thoroughness, and accompanied by an *explanation that has the force of encouragement*, and leaves no doubt as to the physician's conviction, will often clear out the weeds that block the flow of the river of consciousness and let the current sweep along, with the self-obliviousness of healthy activity, in its old channel.

It is a striking fact, as regards explanations, that they have much greater weight after the physician's authority has become established by the partial success of his treatment. The arguments offered beforehand may have been just as convincing as those offered later; so delightfully logical, in fact, that the physician often buttons on his overcoat and leaves the patient's door with the self-satisfied conviction that the battle had been won for both parties. How great then is his surprise, amounting almost to indignation, when he discovers, at his next visit, that not even the outposts of the enemy have been won. Let the patient's confidence have been gained by a little success in treatment, however, and he may accept (sometimes too readily) any explanation, logical or illogical, that the doctor is inclined to offer. All mental healers know this well, and have known it, doubtless, since long before the day when the doubting and suspicious Naaman professed himself ready to accept the religious views of Elisha in return for the cure of his leprosy. The explanations of the doctor are in fact quite as much an appeal addressed to the faith as an argument addressed to the reason.

It will be remembered that Naaman, who was a captain of the host of the King of Syria, was afflicted, according to the diagnosis of the times, with leprosy, and that he was sent by the master to the King of Israel, at the instance of the captive Hebrew maid, to be cured by Elisha the prophet. "So Naaman came with his horses, and with his chariot, and stood at the door of the house of Elisha." Perhaps in his heart he expected failure, and expected it the more that he had pictured to himself just what steps the prophet would take to cure him. When, then, instead of coming down to meet him in person, Elisha left him standing with his retinue at the door, and sent word to him that he should go and wash in Jordan seven times and he would be clean, Naaman turned and went away in a rage, saying, "Are not Abana and Pharpar, rivers of Damascus, better than all the waters of Israel? May I not wash in them and be clean?" And it was only when his servants pointed out to him the folly of his childish passion, saying, in effect, "If the treatment does you no good, it will do you no harm," that he consented to the prophet's

conditions. Consent he did, however, and not only was he cured, but he promptly became a convert to the true faith, and one may suspect that he would have been willing to accept any proposition that Elisha had chosen to offer. This parable, as one may call it, is instructive in many respects besides that of indicating the power which the physician acquires over his patient through his success in treatment. It illustrates strikingly with what complex feelings the patient goes — half trusting, half doubting — to see the doctor, and illustrates, too, how the doctor is sometimes put to his wits to see that he does not discount his authority with the patient by letting him dictate the details of the treatment.

I permit myself to say, however, that such an enforcement of conditions, unmeaning in themselves, although it is an effective device and often a necessary one, represents a means of maintaining authority which every physician should try to eliminate more and more as the relations between himself and his patient become established on a more natural basis. We must cure our patients if we can, even if it is necessary to put on the manners of the Grand Pasha, or to hold ourselves as remote as the Mikado; but, on the other hand, something may be risked in the interests of directness and simplicity.

Where simple encouragement and explanation fail, it is often possible to induce the patient, by coaxing or training, to do something which even he must see that he could not have done if his own diagnosis had been correct. If, for example, he has lost temporarily the power to move a limb in a certain way, he can perhaps succeed, under assistance and supervision, in making a sudden motion which will include the lost movement, among others; and then he can be taught to analyze his sensations and to differentiate his efforts. Even pain (in suitable cases) may gradually be cast out if the patient is encouraged to note that "this time," or "that time" it was less severe, until he learns to have an alternate picture of himself as free from it, which at first he did not have. Fortunate it is if the patient can be led to take interest in the "habit" theory, and still more fortunate if he takes to himself the credit of the cure.

Where all these means fail, the physician must make his influence strike deeper. He must himself recognize that one reason for the persistence of habits is that they represent the active intervention of a portion of our consciousness which lies outside the field of our personal attention; beyond the direct reach of our personal will. This hidden consciousness, that plays so active a part in causing our morbid acts, is no stranger, but on the contrary an old friend. The power that thrusts an obnoxious act or thought into the current of our lives is closely related to that power that notes the flight of time during the night, waking the nurse at the appointed hour, or to that which tosses up to us the memory of a forgotten engagement — sometimes, alas, too late — as a chip is tossed up by an eddy in the stream. In the technical language of the day, this power is called "our subliminal consciousness," that which works "below the threshold" of our personal attention. I prefer myself to call it the "sub-personal (or extra-personal) consciousness," but it will be better if you will forget names and seek in your practical experience the warrant for the truth of what I say.

THE "RIGHT-ANGLE" CONTINUOUS INTESTINAL SUTURES.[1]

BY HAYWARD W. CUSHING, M.D., BOSTON.

THE ideal intestinal suture is the one which combines greatest rapidity in formation with maximum security from extravasations of intestinal contents. To fulfil these requirements there must be exact adaptation of wound edges and an accurate apposition of serous surfaces; also simplicity in construction, since ease in application means rapidity in operating, and adaptability to general use demands a technique uncomplicated, readily understood, and requiring only such materials and instruments as are commonly at hand, or easily to be obtained.

A short experience usually demonstrates that "continuous" sutures have a great advantage in regard to the ease and rapidity with which they can be inserted. The time spent in knotting a fine wet thread, with fingers sticky with blood, in an intestine difficult to hold as a wet rag, is surprisingly long.

It is true that some other sutures are usually firm, accurate and handsome; but the extra time required to tie twenty or thirty knots is a very important factor in the success of an operation when the patient is rapidly approaching collapse. The result of my observations is that an intestinal wound can be closed from one-third to one-half more rapidly with a continuous suture than by any other form I am cognizant of. In 1886, after many experiments, and an extended investigation of the best sutures then known, I was convinced that the method I then described as the "Right-Angle" continuous was the most satisfactory, other methods being discarded on account of their complex character, or the length of time and especial appliances required for their formation.

The "right-angle" continuous suture is a modification of the Kürschner, or the "continuous Lembert." It has been called by some surgeons a modified "Appolito." It excels not only in neatness of appearance, but also in accuracy of wound union. It is not only continuous but is also a "buried" suture, reducing adhesive inflammation to a minimum. It can, with some practice, be applied easier than other sutures. It can be applied *more rapidly than other sutures* with scarcely an exception — a point of great importance. One of many trials is the following: Resection of human ileum; Lembert sutures required fifteen minutes; the continuous "right-angle," two experiments, five and nine minutes. I have united a resected ileum in the living human subject in eight and two-thirds minutes. With this suture the greater the distention of the intestine the closer the edges of the wound are approximated. It can be interrupted at any point, if desired. It can be reinforced by another superimposed, if any point seems insecure either by itself or an "interrupted Lembert."

Its disadvantages are that its technique is not so readily learned as some; for example, the "Lembert." Again, it has been claimed that if there is much intestinal distention constriction occurs, with resulting obstruction to blood circulation and recoveries. I have found no record of such a result from a continuous

[1] Presented at the twentieth meeting of the American Surgical Association, Chicago, June 2, 1899.

suture. In my own experiments on living intestine or clinical observations it has not occurred. It is rather an advantage, since the constricting circle is during distention more deeply buried (Fig. 1), thus approximating more extensively the inverted serous surfaces through whose union, mainly, fecal extravasation is averted. With the Lembert the reverse is true. The sutures separate as the intestine distends and its circumference increases. The inverted edges become narrower by this stretching and are in danger of everting and prolapsing outward between the sutures. Fecal extravasation is then possible.

In regard to septic infection and suppuration along the track of the suture while being cast off into the lumen of the intestine, I know of no case where this has occurred. The experiments on animals show that the sutures may be partly exfoliated and hang free in the lumen of the intestine without causing septic inoculation of the wound, which has united long before the suture is thus freed, which requires from two to three weeks.

After an extensive review of the literature of the subject, careful and extended experimentation with living animals, practical tests and experiments with various sutures in the dead human intestine, and from personal observation during years of hospital service I concluded that the most satisfactory sutures in most cases was the "right-angle" continuous, reinforced by a similar one superimposed; or by an "interrupted Lembert," if isolated points only require to be secured. If the suture is properly made, this reinforcing will be, as a rule, unnecessary. The reasons for this conclusion are:

(1) The suture does not involve the mucous membrane.

(2) The intestine is closed by a suture which acts so that the greater the tension to which it is subjected the closer it is drawn.

(3) It can be inserted very rapidly and easily.

(4) The closure of the intestine is impervious and efficient.[2]

(5) Its technique is simple.

In proof of the efficiency of this suture I desire to report a few results, recently collected, where it has been used by other surgeons [3] than myself. It is not a complete report of the clinical history of the method, for I have as yet made no effort to obtain such. I readily obtained records of twelve cases (including one case of rupture of the bladder), which include four resections,—two cecum, one ileum, one not stated,—four wounds, tears, ruptures or stabs, — one case, nine wounds of small intestine, — two fecal fistulæ, one stomach anastomosis.

Of these patients 75 per cent. recovered. In the fatal cases the wound was found closed or united in all except one, where the cause of death was pulmonary embolism. Here there had been distention of the intestines, so extreme that several of the reinforcing layer of Lembert sutures had been torn out. The "right-angle" suture had also torn through at this point. These are not selected cases, but are reported as they were collected. Some of the patients, exclusive of the fatal cases, were desperately ill.

[2] In hydrostatic tests during experimental work the intestine ruptured at other points, usually along its mesenteric border, before the suture tore out enough to permit leaking.

[3] These results are from the records of Drs. H. L. Burrell, F. S. Watson and J. C. Munro, through whose courtesy I am able to report them.

The length of time to close the intestine is interesting.

For the tears and wounds, that is, longitudinal sutures, the average was six and one-half minutes. One wound, two inches long, was closed in two minutes. One, two inches long (operation fecal fistula), required fifteen minutes — the maximum. The resection wounds averaged ten minutes without the reinforcing suture. In one case the second continuous suture was placed in four minutes. I therefore think it is fair to assume that the above data demonstrate that one can expect to close, with this suture, an ordinary intestinal wound or tear in six to seven minutes, or unite a resected gut in ten minutes. That when so united it will hold, if not better, at least as well as the best methods we now have at our command.

The technique of the perfected "right-angle" continuous suture is as follows: For uniting longitudinal wounds it is inserted as shown in Figs. 2 and 3. The most satisfactory results are obtained in the human intestine by placing the points of puncture one-eighth of an inch (3 millimetres) apart, and by burying the suture to the same extent in a direction parallel to, and three-sixteenths of an inch (4–5 millimetres) distant from, the wound edge. The needle traverses the tough fibrous submucous layer, and is not intended to involve the mucous membrane or penetrate the intestinal cavity. Each stitch of the suture should be drawn tight, so as to accurately appose the wound edge before the next is set.

A resected intestine is united by the same suture, but formed as follows: It is begun at one side of the mesenteric attachment by an inverted Lembert suture, which is tied, and the free end (Fig. 4*a*) left pendent from the knot.[4] The resected edges are now united by the "right-angle" suture, which is inserted in the same manner as in a longitudinal wound, commencing at the point of union already made, crossing the mesenteric attachment (Fig. 5) and continuing along parallel to the resected edges of the gut, till the free end (Fig. 4*a*) at the point of commencement, is reached. Care should be taken not to increase the distance of the suture from the resected edge, thus inverting a wider border. The suture also should not be drawn so tight as to pucker or diminish the intestinal circumference. The union of the "terminal" end with the "initial" free end (*a*) by a square knot (Fig. 6) completes the suture, the (free) ends of which are now cut close to the knot (if silk, one-tenth inch, 2 millimetres, long), which sinks out of sight between the approximated serous surfaces. The completed suture presents the appearance shown in Figs. 1 and 7. The mesentery is united by inverted Lembert sutures, interrupted, set on each peritoneal surface (Fig. 7). A very thin mesentery is best sutured by an ordinary interrupted suture. Continuous sutures, when of any length, have been found at autopsy to have relaxed and allowed the mesenteric wound to separate.

For the suture I use the finest white silk, "Machine

[4] By commencing the suture at one side of the mesenteric attachment as above described (Fig. 4*a*), that portion of the wound is united first, and at a time when it is most accessible. The advantage of this is self-evident, since this is the most difficult point to unite securely, and at which fecal extravasation is most apt to occur. Also when completing the suture the operator can make the last few stitches and tie the final knot in full view, at a point easily accessible, instead of at one so concealed and difficult of access as that portion of the wound about the mesenteric border, the site frequently selected for the completion of an intestinal suture.

twist," J. D. Cutter, No. 000, sterilized by boiling, preserved in sublimated (one-tenth per cent.) alcohol (95 per cent.).

The best needle is a "self-threading" or "spring-eyed" round sewing-needle, one and one-sixteenth inches long. By having this ground flat like a "Hagerdorn," an instrument is obtained which combines all the advantages of the round needle usually used, and is far superior to it, on account of the ease with which it traverses the intestinal wall.

THE EXAMINATION OF STAINED SPECIMENS OF BLOOD IN ITS APPLICATION TO CLINICAL WORK.[1]

BY HENRY F. HEWES, M.D., BOSTON.

(Concluded from No. 2, p. 41.)

A STUDY of the white corpuscles of blood may, like that of the red, be of considerable importance in connection with the study of our clinical cases. As we have described, in normal blood the leucocytes are present in a certain definite number, the limits of the normal variation being, in the fasting condition, between four and eleven thousand per cubic millimetre of blood. This total number is made up of three and only three distinct types of leucocyte, the distinguishing feature of each type being the staining reaction of the granular cell protoplasm. Each of these three types of leucocyte is present in a certain proportion one to the other. The changes in the characteristics of the leucocyte picture which we find in pathological conditions include variations in one or all of the above conditions or essentials. That is, we may have abnormal varieties of leucocytes in the blood or an abnormal proportion of some one of the normal leucocytes, or an abnormal number of leucocytes present in the blood (the peripheral blood).

There are several forms of leucocyte found in the blood of pathological conditions which are never seen in normal blood. Of these there are two forms which may in the present knowledge of pathology have a practical significance for us in clinical work. These are the two forms of *myelocyte*, the neutrophilic and oxyphilic.

The *myelocytes* are so called because they resemble, and probably are, cells native to the bone marrow. These myelocytes resemble to some extent the normal neutrophiles and oxyphiles, which are in all probability developed directly or indirectly from them or similar cells. They differ from these normal leucocytes, their derivatives, however, in several characteristics, of which the chief is the character of their nuclei.

The normal neutrophile (the polymorphonuclear neutrophile) with its ameboid character has an irregularly-shaped nucleus. It may be horseshoe-shaped or may appear as several nuclei (polynuclear leucocyte). It is never round (practically).

The neutrophilic myelocyte is a round nuclear, neutrophilic cell. The nucleus is spherical, of less intense stain than that of the normal neutrophile. It occupies, as a rule, three-fourths of the cell, and is well marked off from the surrounding protoplasm. The protoplasm is studded with neutral-staining lilac granules, similar to those of the normal neutrophile. In size this cell is, as a rule, large, but it may be of any size. It is non-ameboid. This cell is found in health in the red marrow of the bones. According to Ehrlich, here these cells can be found in all stages of development from basophilic tissue cells, and here also may be seen all stages of development of the normal neutrophile from these myelocytes. In this connection it is interesting to note that myelocytes in the blood can by appropriate staining frequently be made to show both neutral and basic granules in the protoplasm, while with the same staining process the normal neutrophile shows the neutral granules alone.[8]

The differences between the oxyphilic myelocyte and the normal oxyphile are on the whole the same as those distinguishing the neutrophile. The granules of the oxyphilic myelocyte are, however, much larger and darker staining than those of the normal cell.

Neutrophilic myelocytes may occur in the blood of a considerable number of pathological conditions. They are generally present in small numbers wherever a neutrophile leucocytosis occurs, as with the leucocytosis of infectious diseases, suppuration, etc. That is, apparently in the exodus of the marrow stores of neutrophiles in response to the chemotactic influence present in these conditions, some of the myelocytes are carried out. In rare cases of pneumonia and diphtheria as many as 10 to 15 per cent. of the cells have been found to be myelocytes. This myelocyte is most in prominence, however, in conditions of myelogenous leukemia. Here it occurs in such numbers, often 20 to 50 per cent, and associated, as a rule, with so great an increase in the total number of leucocytes that a pathogneumonic blood picture of myelocytosis is presented.

The oxyphilic myelocyte is found in the blood in cases of myelogenous leukemia. It is rarely found in other conditions.

There is one cell which occurs in small numbers in normal blood, which is found in considerable numbers in some pathological bloods. This is the mast cell. This cell is a basophile with this modified Ehrlich method of staining, and we do not distinguish it from other basophiles in our classification. The mast cells are large cells with a fragmented or three-lobed nucleus and a protoplasm studded with large basic granules. This cell is a common feature of the blood of myelogenous leukemia.

An actual increase in the number of leucocytes in the blood is a symptom of a great variety of conditions. Such an increase is almost invariably associated with a relative as well as an absolute increase of a particular form of leucocyte. A relative increase in the proportion of one or more normal or abnormal forms of leucocyte, occurs in a great number of conditions. It may or may not be associated with an actual increase in the number of leucocytes. This subject of the absolute and relative increase of the various leucocyte forms will be taken up in the study of leucocytosis.

In its broadest sense the term *leucocytosis*[9] means an increase in the blood of the actual number of any of the several varieties of leucocyte. Such a condition may occur with or without an actual increase in the total number of leucocytes. It is rare, however, that the existence of a leucocytosis, unaccompanied by an increased total number of leucocytes, has any distinc-

[1] Introductory lecture to the course in hematology at the Harvard Medical School.

[8] Normal neutrophiles have sometimes basic granules, but it needs a stronger basic stain to color them.

[9] Several writers, as Cabot, restrict the term leucocytosis to the condition in which there is a proportional increase in the number of normal neutrophiles in the blood, but its general application is as given above.

tive significance for purposes of clinical diagnosis. In our study of the leucocytes in connection with clinical work, therefore, we are interested principally in those conditions in which we have an actual increase in the total number of leucocytes.

These leucocytoses may be physiological or pathological.

Physiological leucocytoses are slight increases in the number of leucocytes occurring under the influence of physiological conditions, as during digestion, or exercise, or in pregnancy. Such leucocytoses show either an unchanged differential count or an increase of neutrophiles — a neutrophilic leucocytosis. (I have seen digestion leucocytoses with a normal differential count, others with a neutrophile leucocytosis.) The influence of such conditions can be excluded in a given case by proper choice of the time for taking the blood.

The pathological leucocytoses show some variation in the proportion of some normal or abnormal form of leucocyte. They may be classified in accordance with the nature of the leucocyte to the proportional increase of which the actual increase present is principally due.

In a classification formed upon these lines we have the following forms of leucocytosis:

(1) Basophile leucocytosis.

(2) Neutrophile leucocytosis. (*a*) Polymorphonuclear neutrophile leucocytosis; (*b*) round nuclear neutrophile leucocytosis (myelocytosis).

(3) Oxyphile leucocytosis.

In the basophile leucocytosis the actual increase of leucocytes is due principally to a proportionate increase of basophiles.

The marked increase in the total number of leucocytes with a high differential proportion, 50 to 95 per cent., of basophiles is the distinctive feature of the blood of the disease known as lymphatic leukemia. In this condition we may see many morphological forms of basophile in the blood, round nuclear, polymorphonuclear and apparently polynuclear forms, often of all sizes.

A basophile leucocytosis may, however, occur in several other conditions — but except in children it is, leukemia excluded, rarely associated with any marked increase in the total number of leucocytes. A simple proportionate increase of basophiles is found in pernicious anemia, rhachitis, typhoid fever, and many conditions of inanition and anemia. As we have said, where it is not associated with an actual increase in the number of white corpuscles, no great importance, in the present light of medical knowledge, can be attached to it. Children under ten years of age have normally a per cent. of basophiles running between 50 and 80 per cent., the proportion decreasing with the age. In a child it is not rare to get an increased white count with basophile leucocytosis as a secondary feature of many diseased conditions.

In a neutrophile leucocytosis the actual increase may be due to a proportionate increase of either of the neutrophilic cells which occur in blood, the normal polymorphonuclear neutrophile or the neutrophilic myelocyte. Often both types share in the increase.

In the vast majority of neutrophile leucocytoses, such as occur with infectious diseases, with suppuration, etc., the increase is almost entirely in the normal polymorphonuclear type. The number of myelocytes present in these cases rarely exceeds one per cent. In a few cases of pneumonia and diphtheria they have been reported as high as 10 to 15 per cent. But as a rule in these leucocytoses it is evident that the normal neutrophile is the prominent factor in the condition, the myelocyte being but incidental in the picture. This is the type of leucocytosis which is most common. The term leucocytosis is limited by some writers to this type (Cabot).

In one type of neutrophile leucocytosis, however, we meet with a very different picture. Here, although both forms of neutrophile are greatly increased in number, the myelocytes are prominent in the picture. This is the leucocytosis associated with the condition known as myelogenous leukemia. Here we have as a rule a very great increase in the total number of leucocytes, much greater than is the rule in the common neutrophile leucocytosis. And in every field we find myelocytes — so that these cells often form in the differential count from 15 to 50 per cent. of all cells present.

The normal neutrophiles, on the other hand, though their number is actually increased, show a diminished relative number, their per cent. often falling to 30 or 40 per cent.

Although, as you see, it is impossible to draw an absolute line between these two forms of neutrophile leucocytosis on paper, both being mixed leucocytosis, yet it is seldom difficult in practice. Thus we cannot say that all neutrophile leucocytoses with less than five per cent. of myelocytes are simple secondary leucocytosis, while all with over five per cent. are myelogenous leukemia. But one quickly comprehends in a given case whether the myelocyte is the important factor or merely an incident in the condition.

There is a general picture in myelogenous leukemia — leucocytosis with myelocytosis and anemia — which is characteristic. Blasts are often plentiful. Mast cells are commonly seen, as are several abnormal forms of leucocyte other than the myelocyte. In addition, the oxyphile cells, which are relatively and actually decreased in a simple neutrophile leucocytosis, are actually and sometimes relatively increased in myelogenous leukemia.

In an oxyphile leucocytosis (eosinophilia) there is an actual increase in the number of oxyphiles in the blood. In myelogenous leukemia this increase is due in great part to the presence of oxyphilic myelocytes in the blood. In all other conditions of oxyphilic leucocytosis, however, with very rare exceptions, it is the number of normal polymorphonuclear oxyphiles which is increased. This oxyphile leucocytosis is found in a variety of conditions. It is found in asthma, pemphigus and several skin diseases, helminthiasis and as a post-febrile phenomenon. (Scarlet fever is the only acute febrile condition in which it occurs during the febrile stage.) It is found in trichinosis. Here 50 per cent. of oxyphiles have been reported. An actual increase of oxyphiles is said to be always present in myelogenous leukemia. As stated here, we find the oxyphilic myelocyte present increasing our oxyphile count. In these cases of oxyphilic leucocytosis the actual increase is not always accompanied by a relative increase. This is notably the fact in leukemia, where the great increase of neutrophiles is out of all proportion to the increase of oxyphiles.

To determine the existence of this actual increase in a particular form of leucocytosis it may be necessary to carefully count a given number of microscopic fields,

as measured by a micrometer eye-piece. For the details of calculation of the number of leucocytes by this method the reader is referred to Ehrlich.[10] It is rarely necessary to resort to this method for purposes of clinical work.

The characteristics of a given form of leucocytosis, the increase in number of leucocytes and the variations in kind and proportion can be recognized with facility by the method of examination of stained specimens. To judge of the presence of an increased number, some practice in estimation of these stained specimens may be necessary. Frequently the increase is so marked that one is aware of it at a glance. Where the increase is slight, however, or less than 100 per cent., that is, where the number of leucocytes per cubic millimetre is less than 15,000 to 20,000, a careful estimation of the slide is necessary. To properly carry on such work we should have practice in the examination of even spreads of normal blood and of blood possessing various degrees of hyperleucocytosis. With such training one can judge of the existence of even a moderate increase, a leucocytosis of 15,000, with fair accuracy, and even approximate the actual count. In estimating this question of a leucocytosis and its extent in doubtful cases it is best to count systematically the number of leucocytes in a given number of microscope fields upon your specimen and compare this record with that made from a specimen of normal blood spread with same thickness, and perhaps with records of specimens of bloods with varying degrees of leucocytosis, which have been obtained by white counts.

By a comparison of the findings on your given specimen with records of the findings of the preparations of blood containing 5,000 or 8,000 or 11,000 leucocytes per cubic millimetre, the normal variation, you can tell whether the number of leucocytes exceeds these limits or not. Also, after practice of the same kind in recording the findings of specimens in which different degrees of leucocythemia are present, you can judge by comparison of your actual number of leucocytes in your case. In cases where the finding leaves you in doubt a white count can always be made. Frequently, however, all that you desire to know is whether an increase exists or not. At all events even with moderate practice your cover-slip examination saves you the trouble of a count in many cases by showing a normal condition; it gives you positive evidence of a hyperleucocytosis in cases where the increase is marked; it gives you at the same time that it reveals the leucocythemia the diagnosis of the kind, whether basophilic leucocytosis, leukemia, etc., which the white count does not do.

It is not the purpose of this lecture to enter into a discussion of the theoretical side of the physiology and pathology of blood. Some consideration, however, of the present views concerning the origin of the leucocytes and of the mechanism of the production of the various leucocytoses may be useful in preparing for a clearer understanding of these leucocytoses in practical work.

Our knowledge concerning the origin of the leucocytosis of blood is very unsatisfactory. In regard to this question there are two principal theories:

The first is that the three common forms of leucocyte, the basophiles, neutrophiles and oxyphiles, represent different stages in the life development of a single cell, which begins its existence in the blood as a basophile (lymphocyte) and there develops to a neutrophile and finally to an oxyphile. It is not necessary by this theory that the development occurs generally in the blood. It may occur in part in certain centres where the basophiles are carried and from which they emerge as neutrophiles. But the single line of origin is maintained. The seat of origin of the original basophile is considered to be in part the lymph glands and in part the bone marrow.

The second theory is that the different forms of leucocyte originate separately in several centres and enter their blood existence as basophiles, neutrophiles and oxyphiles, full-fledged.

According to the promoters of this theory, the basophiles enter the blood principally from the lymph glands, wherever found, in the intestinal membranes, spleen, or lymph channels; in small part from the bone marrow. The neutrophiles originate exclusively from the bone-marrow centres, where they are formed from original basic cells, passing in their development through the stage of the round nuclear neutrophile or myelocyte, and becoming finally ameboid polymorphonuclear cells. The oxyphiles also arise in the bone marrow through a process similar in its features to that of the neutrophile.[11]

By either theory the centres of origin are almost exclusively the bone marrow and lymph glands, the spleen playing a very unimportant part in the manufacture of leucocytes.

The myelocytes originate in the bone marrow.

The mast-cell basophiles originate in the marrow from tissue cells and may also to some extent be formed from connective-tissue cells elsewhere.

There are also two views in regard to the actual process of leucocytosis: The first is that all forms of leucocytosis represent an actual increase in the numbers of leucocytes of one or more particular types of leucocyte in the blood.

The second theory divides the leucocytosis into two classes. In the first class, including such leucocytoses as occur in the leukemias, there is an actual increase in one or several forms of leucocyte in the blood. In the second class, including the common neutrophile leucocytosis of suppuration, infectious diseases, etc. (the leucocytosis of Cabot), there is merely a change in the distribution of the leucocytes already in the blood, great numbers of neutrophiles being attracted from the internal to the peripheral circulation.

According to Ehrlich, the influences which govern the process of leucocytosis are of two distinct kinds, as follow:

The leucocytoses in which the ameboid forms of leucocytes, the polymorphonuclear neutrophiles and oxyphiles, are increased are as a rule brought about by chemotactic influences. The toxin of bacterial infection, etc., attracts these cells forth in greater numbers from their centres of development, perhaps stimulates their development.

The influence which brings about the leucocytosis with an increase of the non-ameboid cells, the basophiles, as that of lymphatic leukemia, is a mechanical one. There is an increased production of these cells in the blood centres, an increased flow of lymph through them, and great numbers are swept into the blood stream.

[10] Die Anemie, p. 20.

[11] Klein, Cent. f. Inn. Med. 1899, believes that all oxyphiles are developed from other leucocytes by the laying down of granules formed from broken-down hemoglobin.

The leucocytosis of myelogenous leukemia is principally mechanical, but perhaps also due to some extent to a combination of both influences — a mixed leucocytosis in the sense of its causation as well as in the nature of its cells. Some morbid process, in some cases perhaps chemotactic influences, may stimulate excessive development of cellular elements in the bone marrow. With the increased activity, numbers of cells are swept into the blood stream, both myelocytes and ameboid neutrophiles. Chemotatic influences may also here be a factor in attracting the ameboid cells to the blood.

Evidences of special chemotaxis, the attraction of the toxins (?) of special conditions for special forms of leucocyte, are numerous. Thus in cases of lymphatic leukemia where the blood contains 95 per cent. or more of basophiles, in which some suppurative process develops locally, the pus contains neutrophiles as in cases where the blood content is normal. In a case of Duhring's disease reported by Leredde and Perrin the exudate fluid of the vesicles, which had contained oxyphiles only, became infected with bacteria, upon which the oxyphiles of the exudate were replaced by neutrophiles. Neusser, in a case of pemphigus in which the vesicles contained oxyphiles, induced by a vesicant an inflammatory process in several vesicles, whereupon the cell contents of the vesicles changed from oxyphiles to neutrophiles.

This review of the method of the examination of the stained specimen of blood, the description of the appearances of the corpuscular elements of blood in the normal individual or under the influence of various pathological conditions, as studied by this method, indicates clearly, I think, the general lines of usefulness of this method in clinical work.

In the first place, we are able by the application of this method to diagnose the existence of an anemia in a given case; to estimate the severity of that anemia and to determine its type. The appearance of degenerative changes in the red corpuscles, of achromia or poikilocytosis one or both, at once proves to us the presence of an anemia. The extent of these changes, the appearance or non-appearance of blasts, aids us in determining the severity of the condition.

Having thus determined by inspection the existence of an anemia, we next determine its type, whether pernicious anemia or secondary anemia.[12]

The characteristics of the blood of pernicious anemia are (1) a marked poikilocytosis, with a tendency to an average increase of size in the red corpuscles, and (2) the presence of blasts, of which the greater number are megaloblasts. Achromia is rare, though it may occur. If, therefore, in a careful study of several specimens we find such a poikilocytosis, and nucleated reds present in small or large numbers, and in a count of these blasts find more megaloblasts than normoblasts, we diagnose pernicious anemia.

Some, but slight, confirmation of this diagnosis can be obtained by the finding of a normal or increased color index, from a comparative estimation of the hemoglobin and the number of red corpuscles present.

[12] It is possible also from our blood finding to divide the secondary anemias into two types. Thus if in an examination of our specimen we find that achromia is the predominant degenerative condition, out of all proportion to the poikilocytosis or other changes, we may diagnose a chloranemia — an anemia in which the color index is very low. This determination can be confirmed if necessary by an estimation of the hemoglobin and a count of red corpuscles, to determine the actual loss in hemoglobin and the color index. But for the simple diagnosis of the condition the slide examination will suffice. This is the type of blood which is found in the disease of young women known as chlorosis.

If in our anemia we do not find a megaloblast type of blood, we have a secondary anemia.

This separation of the anemias into two types by the blood findings is of course an artificial separation. All anemias are secondary; but we can pick out from the many forms one which has in its blood finding a distinctive picture which enables us to classify it by itself. Pernicious anemia, as is clear from our descriptions given earlier of the origin of normoblasts and megaloblasts, is merely a term for a condition of anemia in which the blood-forming centres have reverted to a considerable extent or wholly to the embryonic type of formation of the red corpuscles. This condition may be brought about by several causes. One cause, the infection of the body with the parasites, as the bothriocephalus latus, or the ankylostoma duodenale, we know and can remove. And in such cases the marrow resumes its normal condition and the patient recovers. As to all other causes of this condition we are in the dark. We do not understand their nature and cannot remove them. And it is a matter of experience that all cases with a blood finding of this megaloblast type are progressively fatal. Therefore when we find such a blood we pronounce a case, unless it be one of infection with the before-mentioned parasites, as one of pernicious anemia. The distinction is a thoroughly useful one for purposes of diagnosis and prognosis. I have never seen a case with a blood of this type recover ultimately and know of no such case in literature (except the parasitic cases mentioned).

It is of course impossible to point out here just what the cases are in which the knowledge of the presence or absence of an anemia may be of special importance for diagnosis. But they are many, and since the method determining this fact is so simple it should be investigated wherever there is the least occasion for such a step.

The evidence of anemia which one finds in a large per cent. of cases investigated and found anemic consists in the presence of some achromia, with some distortion in form and size. As a rule the number of corpuscles is normal in such cases. The hemoglobin is, however, reduced. And it should be remembered that the existence of a very mild anemia can sometimes be discovered by this hemoglobin estimation when it is not apparent upon the stained specimen. Anemia is not therefore to be ruled out except by a hemoglobin estimation (specific gravity). If it is of any significant extent, however, it will show in the stained specimen.

In the second place, we may by this method discover the existence of a leucocytosis and differentiate its particular type.

Thus by finding a neutrophile leucocytosis with a considerable proportion of myelocytes we may diagnose myelogenous leukemia, a marked basophilic leucocytosis, lymphatic leukemia.

If we find an unmixed neutrophilic leucocytosis we know that we have present one of the conditions with which this leucocytosis is associated and we can rule out all conditions which do not have a leucocytosis. Such a finding may help us in a given case to differentiate pneumonia from phthisis, suppuration or pyemia from malaria, appendicitis from typhoid, scarlet fever from measles, to diagnose the existence of suppuration, hemorrhage or certain acute infectious diseases, to rule out typhoid or malaria.

If we find an oxyphilic leucocytosis we are led to

consider some condition thus accompanied, as trichinosis, leukemia.

If our blood slide leads us to suspect an increase in the number of leucocytes, and we wish to estimate the exact number, we can make a white count. Where the number appears normal we gain our knowledge without this trouble.

In the third place, we may discover by this method the presence of blood parasites, the plasmodium malariæ, the filaria sanguinis hominis, the spirillum of relapsing fever. It is customary to look for these parasites in the fresh specimen, where they are seen alive. But it is perfectly possible to discover them in stained specimen.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

ON THE RELIEF OF SUFFERING IN LABOR.

W. S. FOTHERGILL,[1] of Manchester, Eng., says that he is convinced that far more than half the actual pain which is suffered in this world is borne by parturient women, and that pain of this kind receives less attention than any other form of suffering. This occurs although relief of pain is one of the first duties of the physician and the thing for which he is usually summoned. The amount of pain during parturition does not depend upon the difficulty and danger of the labor. Many normal confinements are most painful, while, on the other hand, women in great danger often suffer little. Prevention of suffering during labor is accomplished by having the patient in excellent physical condition, giving her plenty of sleep, as much exercise as possible in the open air short of absolute fatigue, ordering nourishing food, only as much as is necessary, frequent baths, avoiding alcoholic drinks and late hours. Constipation must be prevented. Ordinary corsets and garters must be discarded. Walking is the best general exercise. The ordinary ailments occurring during pregnancy should be treated more by rest and less by drugs than under usual circumstances. False labor pains which often occur are more irregular and more continuous than true labor pains. They cause real suffering, and are usually caused by overloading the rectum. Large enemata, two or three, are given for these if necessary, and the patient put into a large hot bath for ten to twenty minutes. Abdominal applications of mustard, sedatives and opium may then be given if necessary.

During the first stage of labor the use of the hot bath and the rectal enema are equally as useful as in the treatment of false pains. His advice is to keep the patient immersed in a hot bath during the greater part of the first stage, with the view of helping the cervix to dilate and of relieving the pains. Friction over the abdomen, application of a binder, change of posture, quinine in five-grain doses, hourly, for three or four doses, are found to strengthen the uterine contractions without increasing the pain. In the first stage, when the patient is becoming nervous and exhausted, and there is little progress made in the dilatation of the cervix, if it is thought best to give the patient rest by sedatives in place of artificial dilatation, he then first administers a little chloroform, just enough to abolish the patient's reflexes, and follows this just before the patient wakes by a hypodermic injection of morphia. She will then sleep on for some time, and will, on awakening, go on with her labor, feeling much better, and frequently a considerable amount of cervical dilatation will be found to have been accomplished unconsciously during her repose. For the nausea and vomiting often quite severe in the first stage, he applies a mustard leaf over the stomach and gives internally a mixture of chloroform, carbolic acid and dilute hydrocyanic acid in water.

During the second stage of labor anesthesia is produced in the usual way, that is, as the pain comes on the anesthetic is administered during a few respirations, without abolishing the reflexes or destroying the consciousness of the patient. This is continued until the birth of the head, when complete anesthesia is desirable. If pains do not come on regularly in the second stage, with one hand on the uterus rub the fundus of the uterus every three minutes until a contraction is brought on. In this way the labor may be quickened. Cramps during labor may be relieved by hard rubbing and massage done by the nurse. Pain in the back during contractions is much relieved if the nurse presses firmly on the sacrum. He protests against a too energetic manner of conducting the third stage of labor, because of pain from prematurely expressing the placenta. In suturing the perineum the pain is caused by the needle passing through skin and mucous membrane; therefore if the muscle and connective tissue are united without passing the needle through the skin or mucosa the operation is almost painless. Otherwise an anesthetic should be given for the operation. He advises chromicized catgut for perineal tears instead of silkworm-gut. After-pains may sometimes be avoided by allowing the patient from the first to turn over onto her hands and knees in passing water, thus allowing the uterus and vagina to empty freely. Severe after-pains require a little opium. Calomel is given as a cathartic, two or three grains, followed by a saline.

LYSOL POISONING FROM POST-PARTUM DOUCHE.[2]

The first fatal case from the use of a dilute solution of lysol is interesting because of the former claims for the non-toxic properties of the drug. The patient, a primipara, was delivered of a seven months' child after a short and normal labor, breech presenting. The patient first had a vaginal douche of four litres of a one-per-cent. solution of lysol, and the temperature rising shortly afterward to 102.2°, the uterus was irrigated with a similar solution. After an injection of one and one-half litres she became restless and comatose, with stertorous breathing and weak and rapid pulse. Irrigation was stopped, and the patient became conscious in a few minutes. The following day the patient was weak and jaundiced, and the urine contained albumin, blood and bile. Four days after there was frequent hematemesis, and the patient was much weaker, dying on the tenth day. The autopsy showed congestion of the dura and medulla, the liver was enlarged, the kidneys showed acute nephritis, and there was thrombosis of the right broad ligament and spermatic vein, and also endo- and para-metritis.

[2] Centralbl. für Gynäk., No. 39, 189

COMPOUND INTRA-UTERINE FRACTURE OF THE FEMUR.

Wilson [3] reports the case of a woman, an epileptic, who bore a child, perfect except for a considerable shortening of the right femur. There was a cicatrix over the anterior aspect of the middle third of the right thigh, there having been evidently *in utero* a compound fracture of the femur, which had united at an obtuse angle. The angular deformity disappeared in the course of a few months and the bone became nearly straight, but with a good deal of shortening. Several theories are advanced for the cause of the fracture. One was that it was the result of an epileptic attack of the mother in the fifth month in which she fell against the stove, but there was no pain following the accident. Another theory was that the fracture was due to a possible blow from the husband, and another that during an epileptic attack the abnormal increase of muscular power of the abdominal muscles would be sufficient to hold the fetus as in a vice with the femur raised up in a position to receive an injury from the spasmodic contractions of the muscles. Writers on the subject of intra-uterine injuries concur in the belief that external violence to the maternal abdomen may fracture the bones of the child without injuring the elastic abdominal walls of the mother.

PUERPERAL SEPSIS TREATED BY CREDÉ'S SILVER OINTMENT.

Jones [4] reports a severe case of puerperal sepsis which developed after an operative labor with a retained placenta, which developed soon after delivery. On the sixth day the patient was curetted under ether, the uterus irrigated with lysol and packed with iodoform gauze without any improvement. From the ninth to the eleventh day the patient grew rapidly worse, having several chills, with temperature ranging from 110° to 105° and pulse very poor, from 120 to 140 per minute. The uterus was very tender, with a foul discharge, and there was profuse diarrhea. There was no peritonitis, but the patient's condition was regarded as desperate at this time. Later on the eleventh day the patient was given an inunction of Credé's ointment, between one and two drachms being rubbed into the inner surface of the thigh, and this was repeated the next morning and again daily for two days. On the morning after the first inunction the temperature had fallen to from 104° to normal, the pulse from 120 to 90 and the diarrhea had ceased. The patient seemed well except that the uterus was enlarged and tender and there was a profuse perspiration. All other forms of treatment were omitted when the inunction was begun, excepting only quinine and stimulants given internally. His observations agree with Credé's, that the general improvement is sudden and complete, resembling more the results from antitoxin in diphtheria than anything else. Credé has used the ointment in a considerable number of cases of various kinds. In local processes the inunctions are made as far as possible from the seat of the disease. In acute and recent cases one inunction every twenty-four to thirty-six hours is generally sufficient for the disinfection of the system, while in chronic cases it is necessary to repeat them morning and night for several days.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

MEETING OF THE SECTION ON SURGERY AND ANATOMY, COLUMBUS, O., JUNE 6, 7 AND 8, 1899.

(Concluded from No. 2, p. 47.)

DR. BROWN, of Illinois, arose at this juncture and said: As a representative of the country doctor, who is a listener probably more than anything else, I want to say that this discussion, like every other surgical method in treating disease, leads one to believe that our magnificent surgical friends, Drs. Ochsner and Murphy, are getting on two sides of the question, when in reality they are not. The story I am reminded of is that of the student who was questioned by the professor concerning the treatment of a certain difficulty, as to what he would do — he would do this, and that, and the other thing. "If you didn't succeed then," asked the professor, "what would you do?" He replied, "I would send for you!" The country doctor cannot send for Dr. Ochsner and Dr. Murphy. I should be compelled to send for both of them, because they have two kinds of treatment. This treatment of cases of peritonitis is simply a matter of the individual case. When Dr. Ochsner goes to the bedside of a patient he will treat that individual case as he finds it, not as you discuss it here before these gentlemen. Dr. Murphy will do exactly the same thing. I know the treatment of Dr. Ochsner of depriving the patient of all nourishment is a good thing, but whether it will do all he says, I am willing to wait to see.

DR. MOORE, of Indianapolis, closed the discussion.

TEMPORARY LIGATION OF THE COMMON CAROTID ARTERY, DURING REMOVAL OF LARGE TUMORS ABOUT THE FACE, WITH REPORT OF A CASE.

This paper was read by DR. JOSEPH J. BRANHAM, of Baltimore. He reported a case of large sarcoma of the face and temporal region; excision; hemorrhage controlled by temporary closures of the common carotid artery by means of a compress and ligature. After operation the patient was up on the fifth day and out of the hospital on the eighth. The most important thing in connection with the case was the manner of controlling the hemorrhage during the operation; the size and position of the growth made excessive hemorrhage inevitable on attempting its removal.

DR. F. C. SCHAEFER, of Chicago, read a paper on

GOITRE: ANATOMY, PATHOLOGY, AND TREATMENT.

He reported seven cases, six of them representing the past year's operative work for goitre, and the other of a large goitre and exophthalmos. He said that there were two remedial agents that loom up so prominently before the profession that it might be of interest to name them: first, the product of the thyroid gland, and second the chemically pure iodine — the former of recent introduction; the latter having been used empirically, locally and internally for many years.

In discussion, DR. WAHRER, of Ft. Madison, Ia., said that he had a patient, a young lady, twenty-four years of age, feeble, with a large unilateral right-sided goitre, as large as a hen's egg. He gave her twenty-five grains of the desiccated thyroid daily, divided

into five doses, with the catophoric application of potassium iodide. The case was treated with marked success. With the continuous use of these remedies, the growth disappeared within five weeks.

In reply to the discusser's question as to the cause of its rapid disappearance, Dr. Schaefer said he thought it was due to stimulation by absorption.

The paper was further discussed by Dr. Levings, of Milwaukee.

Dr R C. Dugan, of Eyota, Minn., read a paper on

EMERGENCY SURGERY WITH ESPECIAL REFERENCE TO WORK IN THE HOMES OF THE POOR.

Discussed by Dr. Brown, Ill.; Dr. Lawless, Toledo; Dr. Rosenthal, Mo.

Dr. J. B. Murphy, of Chicago, read a paper on

INTESTINAL FISTULÆ.

It was very important to the surgeon, it was annoying, it taxed his ingenuity; as a rule it is the result of the surgeon's work. Bone is the most common cause of fistulæ; next is mural strangulation. He divided fistulæ as follows: *Intentional.* — Artificial anus (permanent), artificial anus (temporary), laceration of intestine, impairment of wall, division with scalpel or scissors, forceps, ligature, drainage-tube and packing, injuries in parturition, curettement through perforation of uterus. *Accidental.* — Criminal abortion, vaginal intestinal perforations, failure of union after enterectomy or enterorrhaphy.

In discussion, Dr. L. Crile, of Cleveland, asked what disposition, if any, he undertakes to make of fistula due to tuberculosis of the bowel.

Dr. Murphy replied, resection of the bowel, and recited a case reported by Dr. Körte, in which he operated something like eight times, removing a large portion of the ileum, all of the ascending and a portion of the transverse colon, and finally made an end-to-end anastomosis so as to sidetrack the intestine involved, removing it, and was successful in curing his patient.

Dr. D. L. Fairchild, of Clinton, Ia., read a paper on

SURGICAL TREATMENT OF ABSCESS OF THE LUNG.

He said pneumonia is now generally recognized to be an infectious inflammation of the lungs, due, in the majority of cases, to the influence of the diplococcus pneumonia of Fräukel. The disease pursues generally a well-defined course, marked by certain pathologic changes; once in about 50 cases it is said that the pathologic changes result in the formation of abscess. Among the complications may be found consolidation of the lung, hydrothorax, empyema or abscess. An abscess of the lung is a much more dangerous condition than an empyema, on account of the difficulty of surgical drainage. He reported two cases, one in a man weighing 250 pounds, who was attacked with croupous pneumonia two months previously. After operation patient made a rapid and uninterrupted recovery. The other was a case of a young man who had passed through a rather severe attack of pneumonia. Result, uninterrupted and rapid recovery. He recommended puncture of the suspected area by means of an aspirating needle; if pus is found it should be evacuated by free incision, resecting a rib, if necessary, to obtain sufficient drainage. He did not approve of irrigation, owing to the resulting distressing irritation of the lung.

Discussed by Dr. Levings, of Milwaukee, who advised the use of a short exploratory needle.

Dr. Murphy, of Chicago, spoke of the ease of operating for abscess of the lung with pleural adhesions.

SOME OF THE RARE FORMS OF HERNIA AND THEIR RADICAL TREATMENT.

was the title of a paper by Dr. R. Harvey Reed, of Rock Spring, Wyo., who spoke of gastric, umbilical, ventral, and labial hernia. He desired to show (1) that all cicatricial tissue must be completely removed; (2) that the most perfect apposition of the separated parts must be secured; (3) that strong, flexible, thoroughly sterilized and absorbable animal tissue should be used for subcutaneous sutures, and that non-absorbable, thoroughly sterilized suture should be used for approximating the integument; (4) that great care should be taken to avoid the possibility of necrosis by shutting off the normal blood supply, and thus not only preventing the absorption of the animal structure, but eventually causing the breaking-down of the adjacent structures, thus deprived of their normal blood supply, which is bound to complicate the case. After having tried different kinds of animal tissues, prepared by different methods for subcutaneous suture, he has obtained the best results from pyoktanine catgut, which he has prepared by his chief nurse under his personal direction. For over two years he has purchased his catgut in the raw form from a firm in New York, which experience has taught him furnished most excellent and reliable form of catgut, prepared first by immersion in ether for not less than four days, then wound on glass spools and immersed in solution of 1 to 1,000 of pyoktanine in absolute alcohol, after which the jar containing the alcohol solution of pyoktanine with the catgut is sterilized for one hour under pressure. Objection to other methods of sterilization is the overhardening of the animal tissues.

Dr. McRae, of Atlanta, reported a case of

DIAPHRAGMATIC HERNIA

which he operated, the result of a stab, penetrating the chest and diaphragm; the other was that of a negro woman who gave the history of having severe attacks of constipation for several years, resulting in obstruction.

Dr. Marcy, of Boston, spoke of the

INFUNDIBULAR PROCESS IN THE NORMAL DEVELOPMENT OF THE MALE SUBJECT IN HERNIA.

He reviewed diagrammatically the anatomy of hernia, with especial reference to the cord. He laid claim to the originality of the Bassini operation. Bassini does not claim to have made a single operation until 1884, while Dr. Marcy claims to have made contributions to this technic as far back as 1870. Speaking of the operation he said: "It makes no matter whose name it has, but I claim that the name be given to the nation whence the operation had its origin!" The material is non-essential, only it must be aseptic and absorbable, and when you have gained these two points you ought to have perfect union.

Dr. Freeman, of Denver, mentioned a case of hernia of the diaphragm, produced by a gunshot wound, seemingly only to penetrate the skin, but ex-

amination revealed a large opening in the chest-wall, large enough to admit fist. Patient died of internal hemorrhage.

DR. KELLY, of Baltimore, urged the propriety of considering American claims in the matter of priority of originality in technic. He said: I use the non-absorbable sutures. When it comes to transplantation of the cord in hernia, getting rid of the weak point in the wall, I want all these gentlemen here to speak not of the Bassini operation, but of the Halsted operation. If you will take a little bit of trouble and consult the records, you will see that Dr. Halsted's publication antedated that of Bassini.

DR. LORD, of Omaha, reported a case of

UMBILICAL HERNIA

in a patient weighing three hundred pounds, who had had repeated pregnancies, the last of which resulted in twins. There were two large hernias, one the size of a Bartlett pear, and the other the size of an ordinary hen's egg, between the umbilicus and the ensiform cartilage. I do not recall ever seeing in my researches reference to an umbilical hernia of this kind.

DR. BALLARD, of Louisville, thought that the curved incision offered some points of advantage.

DR. WARNER, of Columbus, urged the early operation of hernia.

DR. MANLEY, of New York, thought the keynote to the situation was that the operation for the so-called cure of reducible hernia ought to be the simplest.

DR. MILLIKEN, of Texas, thought that the silver-wire suture solved the problem.

DR. MOORE, of Minneapolis, wished to bear testimony to the fact that multiple ventral hernias occurred above the umbilicus.

DR. OCHSNER discounted the idea of priority of claims to operations, and thought that the important point was a radical operation, and "not to fool away any time about this man and that man."

DR. RUTH, of Keokuk, said that despite all care he had taken with absorbable and non-absorbable material, he had a great deal of trouble occasionally with infection.

DR. MURPHY, of Chicago, reported a

METHOD OF CLOSING AN OPENING IN DIAPHRAGMATIC HERNIA IN THE CASE OF A BULLET WOUND.

DR. HARRIS, of Chicago, said that all methods which transplanted the chord were bad; he also pointed out the value of the silver-wire longitudinal suture and said that it was removable; that it secured the most perfect coaptation and afforded the best union.

DR. RAMON GUITERAS, of New York, presented a paper entitled

SOME OBSERVATIONS ON THE BOTTINI OPERATION FOR PROSTATIC HYPERTROPHY.

He reviewed the etiology, normal and pathological anatomy, macroscopic and microscopic conditions, symptomatology, prognosis and treatment. He believed in trying palliative measures first, that resection, castration, etc., had all had their day and their advocates. He then gave a description of the Bottini instrument and operative technic. Bottini operated on 200 cases, only 23 of which received any value; no deaths. Meyer, he said, had 12 cases, 4 of which were fatal; Friedenberg had 32; Stein, 12, all improved; Simon, 8, 2 fatal; Hank, 5, fair result; Morton, the same; Clark, 4 cases, fair result; Guiteras, 20 cases, 2 deaths.

In discussion, DR. FREEMAN, of Chicago, reported 7 cases with no deaths; 6 had large, rather firm, prostates, about the size of a lemon. In the seventh case, he said, the prostate could not be felt through the rectum, the middle lobe being large and valvular. All had been very much benefited by the operation.

DR. ROBBINS, of Michigan, reported 4 cases, and said that while he thought it was one of the valuable operations of the future, at the same time he believed that it was a dangerous operation, unless the operator was extremely careful.

DR. BOUFFLEUR, of Chicago, said that he saw a man's entire urethra split by the Bottini operation, and this in the hands of a celebrated surgeon, the blade having turned to the side. He further said: "If the cauterization of the prostate is so valuable, why do it in the dark? Why not make a suprapubic incision, take the cautery and burn the prostate through the bladder?"

In closing the discussion, DR. GUITERAS said that the bending of the blade was a very important point, and that it usually occurs when the amount of electric force is off during an operation. Before every Bottini operation, the battery should be recharged. As a general thing, there is enough force in the battery for three operations; sometimes only one.

DR. W. M. BEACH, of Pittsburg, read a paper on

SOME COMPLICATIONS RESULTING FROM RECTAL OPERATIONS.

He named as some of the complications following operations or injuries upon the fixed rectum, first, incontinence; second, stricture; third, elongation of the anal rectum; fourth, ulceration and hemorrhage; fifth, loss of rectal sense-organs; sixth, suppuration and phlebitis. The direct antithesis of incontinence is stricture.

In discussion, DR. PENNINGTON, of Chicago, thought that, while a good many bad results follow operations on the rectum because of the operation itself, that is, operation for hemorrhoids, etc., I think a great many of these evil results, such as stricture, ulceration, hemorrhage, etc., are due to inefficient after-treatment as much as to the operation itself.

DR. MARTIN, of Cleveland, thought that the title of the paper ought to have been, "Bad results of bad surgery."

DR. A. H. FERGUSON, of Chicago, read a paper on

A TYPICAL OPERATION FOR THE RADICAL CURE OF OBLIQUE INGUINAL HERNIA AND ATYPICAL ONES.

He said, in part: A typical operation for the radical cure of oblique inguinal hernia is one that places all the structures involved in the same relationship to one another as they are present in a normal person. The operations that have been hitherto produced to cure inguinal hernia fall far short of being typical. A careful analysis of failures, a painstaking research for hidden truths and a discernment for contestable premises are ever before the surgeon who hopes for more success, new discoveries and lasting operative procedures. Of all the operations that I have performed, it is the simplest and easiest to execute. There is good scientific reason furnished for every step in the operation. The results are excellent so far. The

last eighteen months I have performed my typical operation sixty-four times, counting each case of double hernia as two operations. There have been no relapses so far. Atypical operations for the radical cure of inguinal hernia are all those which do not in the completed operation leave all the structures as they are present in a normal inguinal region.

The following papers were read by title:

"Excision of Rectum for Malignant Disease, without Sacral Resection," by DR. NICHOLAS SENN, of Chicago.

"Colostomy," by DR. J. A. WYETH, of New York.

"Contribution to the Subject of Operative Interference in Perforating Typoid Ulcer," by DR. C. A. POWERS, of Denver.

"Influence of Age, Sex and Race in Surgical diseases," by DR. W. L. RODMAN, of Philadelphia.

"Hernia of the Diaphragm and Report of Cases," by DR. FLOYD M. MCRAE, of Atlanta, Ga.

FOURTH DAY.

DR. S. L. MCCURDY, of Pittsburg, read a paper entitled

DETAIL IN CLEFT-PALATE OPERATIONS.

He said that in all operations upon the mouth or face the patient should be placed in the Murphy position, the operator sitting above the head, and that Fillebrown's method of producing anesthesia is of advantage in all operations on the face and mouth. He held that in every operation upon congenital deformities the preservation of material should be the first consideration, and that in Fillebrown's operation this conservation of tissue was observed. He then described an instrument called a "steel hoe," with a cutting edge on the tip and on both sides, which was devised for the purpose of cutting through the soft tissues well up around the margin of the cleft, and far enough, too, so that when the flaps are hoed from the bone they reach across the chasm. With the cutting sides it is drawn forward to the anterior angle and backward along the margin of the soft palate, as well as the hard, the uvula being readily split to its tip. A self-retaining mouth-gag was likewise described, which can be accurately adjusted to the side of the head without tilting the mouth-gag from the teeth; it is held in position by a head-band. A self-retaining tongue-depressor is attached to the gag; the tongue can be thrown up to any desired position by adjusting a lever which is attached to the gag apparatus. He then showed an improved staphylorrhaphy needle.

DR. VANCE, of Louisville, said that he endorsed the use of this needle, and that he first knew of it as having been used by Dr. Koons, of Kentucky, since 1882. He believed that it was the best staphylorrhaphy needle in use. He said it was a question whether the dentist could not perform these operations better when the cleft ran back to the hard palate.

DR. OCHSNER said that he had performed the Wolf operation on over thirty patients with success, and that the secret of success in these hard-palate operations consisted in making the flaps so loose that it required no tension to hold them in place.

DR. BULLITT, of Louisville, DR. RICKETTS, of Cincinnati, and DR. MCCURDY closed the discussion.

THE TREATMENT OF BURNS.

DR. M. F. LEE, of Columbus, read this paper by title.

DR. LISTON H. MONTGOMERY, of Chicago, followed with a consideration of

TRAUMATIC SHOCK.

He said that the causes and results of traumatic or surgical shock depend upon the amount of constitutional disturbance that has been produced by the solution of continuity. Among the immediate and remote causes that produce shock would be, for instance, the falling of a heavy weight. A blow upon the head or over the spine, be this ever so slight, and whether the injury inflicted is a contusion, or when a wound has been produced, has been immediately followed by concussion or shock, as the surgeon is disposed to diagnose it. One of the very first symptoms of shock is the subnormal condition of the bodily temperature of the patient. In a word, anticipate shock by the administration of morphine, chloral hydrate, or, if the indications require it, give brandy, whiskey, aromatic spirits of ammonia, coffee, or tincture of digitalis, or the hypodermic use of strychnia, if need be; inhalation of amyl nitrite, and if there is hemorrhage and it is under control, have at hand a saline solution of tepid sterilized water. Keep the head lowered and the body in a recumbent position.

DR. WARNER thought that the loss of blood in this matter of shock was an important point. Especially was this true in children.

DR. FAIRCHILD, of Iowa, thought that the question of shock was a very misleading one. He had seen cases of profound injury in which the element of shock was not very great at the time, and again he had seen patients that were not injured severely suffering from most profound shock.

DR. JELKS, of Memphis, found that the extreme pallor might be relieved and shock ameliorated by a lowering of the head.

DR. NELSON, of Chicago, was of the opinion that anything that affected the sympathetic system would produce shock.

DR. BISHOP, of Pennsylvania, held the idea that one of the things to do was to "cure the doctor of shock," that the best way to get reaction was to "quiet the doctor." He thought that there should be differentiation between shock and hysteria.

DR. JONAS, of Omaha, said it was necessary to clearly define shock from injury; that shock was due to overstimulation; that there was the same amount of blood in the system after the shock, and that the introduction of the saline solutions overfilled the vascular system, producing an amount of work that the heart was incapable of performing, and that many patients were thus killed, instead of shocked to death.

DR. EARLE, of Maryland, DR. MEANS, of Columbus, and DR. WARNER closed the discussion.

WOULD SURGERY SUFFER IF IODOFORM WERE ABOLISHED?

DR. E. C. BRUSH, of Zanesville, O., read this paper by title.

DR. WILLIAM JEPSON, of Sioux City, Ia., read a paper on

AUTOMATIC DRAINAGE.

It was discussed by DR. BULLITT, of Louisville, DR. WARREN, of Columbus, DR. FAIRCHILD, of Iowa, DR. DUGAN and DR. EGGLESTON.

DR. THOMAS C. MARTIN, of Cleveland, read a paper entitled

PHANTOM, SEMILUNAR AND ANNULAR STRICTURES OF THE RECTUM; THEIR DIAGNOSIS AND RADICAL TREATMENT UNDER DIRECT INSPECTION.

He said, in part: That the rectal valve constitutes the most hypsometric of the topographic features of the movable abdominal rectum is conclusively proven by the photographic pictures. The specimens from which the photographs were taken were prepared by a method consisting in fixing the cadaver in the knee-chest posture, and pouring melted paraffine into the atmospherically inflated rectum; when the wax had sufficiently hardened, the gut was carefully removed. There are three forms of valvular obstruction: (1) Anatomic coaptation of the valves may establish an abnormal physiologic resistance to the descent of the feces; (2) congenital hyperplasia of the rectal valve is a condition classically described as diaphragmatic stricture or membraneous septum in the abdominal rectum; (3) hypertrophy of the rectal valve constitutes the classic annular stricture of the abdominal rectum. Obstipation was an important symptom. He differentiated between constipation and obstipation.

DR. EARLE, of Maryland, said that if any person doubted the existence of the valves, the same could be verified by placing the patient in knee-chest position and using a Sims speculum.

DR. BURNHAM, of Baltimore, thought that while these valves did exist, their presence was not quite as distinct as the essayist would want to have them.

The paper was further discussed by DRS. BEECH, PENNINGTON, JELKS and MARTIN.

DR. THOMAS YOUMANS, of Columbus, read a paper on

ACUTE GONORRHEA; ITS PREVENTION AND CURE.

DR. THOMAS'S (Pittsburg) method of treating gonorrhea was twice a day at first, then once a day, etc. A temperature of 140° will not kill the gonococcus. It has been said a case in which typhoid existed and at the same time gonorrhea existed, the typhoid fever would kill the gonococcus. I have a patient under my care at the present time who had typhoid fever, but it did not kill the gonococcus.

DR. CAMPBELL, of Chicago, pointedly remarked in discussion: With regard to the prevention of gonorrhea, I would say that the parents should consider it more their duty in the case of marriage to investigate the condition of the prospective groom, and in that way lessen very materially the work of the gynecologist.

DR. PATTERSON, of Philadelphia, said that the one known method of prevention of gonorrhea is "virtue"; that 85 per cent. of the prostitutes of Philadelphia suffered with some form of venereal disease, the greater proportion having gonorrhea. He also stated that in the University of Pennsylvania, department of genito-urinary diseases, they were able to state absolutely when a case was cured and when it was safe for a man and woman to marry.

DR. FERD. C. VALENTINE, of New York, was the next discusser. He said, in part: The doctor began by saying that the majority of males become gonorrheic. He does not go so far as Spencer Wells, who says that every man had a "clap" sometime or other in his life. I believe that only 90 per cent. of men have it and I protest on behalf of man against the slander! From 10 to 30 per cent. of females become gonorrheic after marriage. I believe that to be an underestimate, because in the statistics of 1894 (Berlin), it was shown that of women dead of disease of the reproductive apparatus, 80 per cent. died of gonorrheal infection. How many of these succumbed because of gonorrhea conveyed by husbands who considered themselves cured it is impossible to say, because the majority of men, I think, would not marry until they felt that the woman of their choice would not become diseased through them. Eighty per cent. of the children that went blind in Germany lost their sight from gonorrheal ophthalmia. He pointed out many diseases resultant from gonorrheal infection. He used the 25 per cent. of the stock solution of potassium iodide and kept fresh bottles on hand.

DR. OCHSNER and DR. JELKS closed the discussion.

Papers by DR. B. B. DAVIS, of Omaha, "A Case of Brain Cyst," and DR. J. H. LETCHER, Henderson, Ky., "Mammary Cancer," were read by title.

DR. F. C. VALENTINE, of New York, read a paper entitled

OUTLINES OF URETHROSCOPIC DIAGNOSIS, WITH SPECIAL REFERENCE TO CHRONIC GONORRHEA.

The doctor held that the chief essential in the treatment of chronic gonorrhea is manifestly, as in other diseases, to ascertain its cause. An instrument, he said, was necessary to show the practitioner where the disease lies, and its character; that such an instrument must be simple in construction, easy of use, not prone to get out of order, and always reliable. He believed that the study of urethroscopy on the cadaver was absolutely useless, circulation having ceased, the natural color and consistency of the mucosa gone, offering no means for comparison. He said that the most frequent tumors of the urethra were papillomas and fibrous polypuses; that carcinoma of the urethra was very rare; that Oberländer was first to make an early diagnosis of carcinoma by means of the urethroscope in 1893. His closing thoughts were, that no chronic disease of the urethra can be diagnosed nor intelligently treated without the urethroscope; the technic of urethroscopy is not difficult; that a urethroscope must be easily manageable, of a prime cost, and of a price of maintenance within the means of the average general practitioner. All these requirements, I think, are attained in the little instrument I am demonstrating.

DR. TUCKERMAN, of Cleveland, said that he would like to show an extension of urethroscopy, presenting a photograph and his device. He had for the purpose of vesical examination made a slight modification in the shape of the obturator, making the point at the side instead of in the middle, and by that means, with a little care, the point enters with ease through the triangular ligament into the membranous urethra, and slides easily over the prostate.

The following papers were read by title:

"Use of Distilled Water and Boiling for the Sterilization of Surgical Instruments," by DR. W. K. ROGERS, of Columbus.

"Use of Dental Engine in Surgery," by DR. W. G. A. BONWILL, of Philadelphia.

"The Division Field Hospital," by DR. S. K. CRAWFORD, of Chicago.

"Intestinal Anastomosis without Foreign Body by Means of a Natural Bobbin," by DR. F. B. TURCK, of Chicago.

DR. J. B. EAGLESON, of Seattle, read a paper on

CASE OF PANCREATIC CYST; OPERATION; RECOVERY.

The patient in question was a native of Norway, age 34. In May, 1897, she had a sudden attack of severe pain in the left side in the region of the kidney, accompanied by extreme nausea and vomiting. The attack lasted five weeks. A second attack occurred in July. During the following winter she suffered recurrent attacks. At the operation the usual lumbar incision was made for exploring the kidney, which was found healthy; the tumor could be located as extending from a fixed point just above the kidney downwards and forwards into the abdominal cavity. The tumor when extricated was found to be oval in shape and about twelve E. M. in diameter; it was smooth, dense and hard, resembling a solid tumor on palpation. An opening was torn through the gastrocolic omentum and the tumor wall exposed, which had a dark bluish color resembling a cyst. It was now diagnosed as a pancreatic cyst and I decided upon immediate incision and drainage. An incision one inch long was now made into the cyst and its contents drained out by turning the patient on her left side. The contents were fluid, dark greenish-yellow, quite turbid, with a sourish odor. At the end of six months her health is good and she is able to do her own housework.

DR. R. M. STONE, of Omaha, Nebraska, read a paper entitled

REPORT ON THE SCHLEICH SOLUTION.

He said, in part: Schleich suggested various formulas containing chloroform, ether, and benzin in different proportions. His No. 3 formula was composed of: Chloroform, 30 cubic centimetres; ether, 80 centimetres; benzin, 15 centimetres. This was adapted to major operations and had a boiling-point of 107.4°. Through the courtesy of Dr. C. C. Allison, surgeon-in-chief of the Presbyterian Hospital in Omaha, I have had the chance to give the Schleich solution 200 times. I have now used it in 250 cases all told. The longer I use it the better I am satisfied with its superiority.

In discussion, DR. MURPHY said that he had had Dr. Stone use the Schleich solution in Chicago for him with very excellent results, and that he was well pleased with it.

DR. JEPSON thought that from statistics of deaths from ether and chloroform, and the number of cases that have been given the Schleich solution in this country, he did not think there were yet sufficient data to prove which was the safest anesthetic.

The above being the concluding paper in the Section of Surgery and Anatomy, DR. MURPHY, of Chicago, proposed resolutions of thanks to the Chairman, Dr. Mayo, for the scientific and business-like manner in which he handled the sessions. The proposition of Dr. Murphy was concurred in by the members of the Section rising simultaneously.

DR. MAYO said: "I thank you for this appreciation of my efforts," and then modestly referred to the Secretary, Dr. Harris, who, he said, assisted him greatly in rendering the results obtained.

A motion to adjourn was then made and ordered.

A $250,000 FEE. — Even the surgeons will soon have to envy the bacteriologist. Koch is said to have asked of the Cape Colony Government the modest fee of $250,000 for his work on the Rinderpest. — *Philadelphia Medical Journal.*

Recent Literature.

The Surgery of the Head and Neck. By LEVI COOPER LANE, A.M., M.D. (Berl.), M.R.C.S. (Eng.) LL.D., Professor of Surgery in Cooper Medical College, San Francisco. Second edition. Philadelphia: P. Blakiston, Son & Co. 1898.

Professor Lane, in his book on "Surgery of the Head and Neck," dedicates his book to futurity, and has only the limited hope that a few years of existence will be granted to its pages. We, however, think better of the work than the author. It is written essentially from a personal standpoint and takes up with commendable thoroughness the various affections of the head and neck. It is written in a pleasing style, and is evidently the result of the author's ripe experience, and works that are founded upon experience are not entirely ephemeral. The cuts in the book are curiously antiquated, and, we regret, do not add to the value of the book. We shall look with interest for the appearance of a work from the author on other portions of the body. The book is very readable.

Chemistry: General, Medical and Pharmaceutical, including The Chemistry of the U. S. Pharmacopœia. By JOHN ATTFIELD, F.R.S., for thirty-four years Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc. Sixteenth edition. Philadelphia and New York: Lea Brothers & Co. 1899.

So rapid and extensive is the advance in the science and art of chemistry that this sixteenth edition of Professor Attfield's work, in spite of the fact that two former editions have appeared within the last decade, contains upon almost every page some important additions to the text.

These changes bring up to date the book which of all books upon the subject of chemistry is probably the best adapted for the teaching of the science of chemistry in its applications in medicine and pharmacy. Combined with a thoroughly comprehensive treatment of the subject and a store of general and special information upon chemistry, the book has a teaching quality which is most remarkable.

The system, and the various methods enlisted by Professor Attfield to teach this, from the point of view of the teacher, most difficult subject, may well serve as an example to all writers upon scientific subjects.

The Treatment of Disease by Physical Methods. By THOMAS STRETCH DOWSE, M. D. (Abd.), F.R.C.P. (Edin.), formerly Physician Superintendent Central London Sick Asylum; President North London Medical Society; Physician to the North London Hospital for Consumption and Diseases of the Chest; to the Northwest London Hospital and to the West End Hospital for Epilepsy and Diseases of the Nervous System, etc. Pp. 400. New York: E. B. Treat & Co. 1899.

This work is in reality a later edition under a new title of the writer's lectures on massage and electricity in the treatment of disease. The general style of the book remains the same, but the subject matter has been brought up to date. In addition to chapters on the principles of massage and its method of application are discussions on the special massage of different portions

of the body. Particular attention is given to massage in nervous exhaustion, sleeplessness, pain, melancholia and allied states. One lecture is devoted to the Weir-Mitchell treatment and another to the Manheim treatment in diseases of the heart. A chapter on Electrophysics and another on Electro-therapeutics complete the volume. The book contains much matter foreign to its title. This is notably the case in the chapter on Massage in Nervous Exhaustion, Neurasthenia and Hysteria. This is a decided disadvantage, in our opinion, from the standpoint of the general practitioner. He opens the book to learn the author's ideas on massage in these various diseases and nothing more. Few doctors have time to read books of 400 pages, of whatever character, and especially is this the case in so narrow a field of medicine as massage and electricity. It is only justice to add that for students of massage these digressions into general medicine will prove very profitable, because of the attractive manner in which they are presented. The broad training of the writer, as his various hospital appointments testify, is made evident from the beginning to the end of the volume.

The Newer Remedies. A Reference Manual for Physicians, Pharmacists and Students. Third edition. By VIRGIL COBLENTZ, A.M., Phar. M., Ph.D., F. C.S., etc., Professor of Chemistry and Physics in the New York College of Pharmacy. Pp. 150, octavo. Philadelphia: P. Blakiston, Son & Co. 1899.

This manual contains an alphabetical arrangement of the newer remedies, giving in concise form their synonyms, sources, methods of preparation, tests, solubilities, incompatibles, medicinal properties and doses. In the addenda, special consideration is devoted to organo-therapeutic agents and the indifferent compounds of iron. The book is exactly what it pretends to be, is eminently satisfactory and its third edition is sure to meet with favor by physicians and druggists.

The Crystalline Lens System. Its Embryology, Anatomy, Physiological Chemistry, Physiology, Pathology, Diseases, Treatment, Operations and After-Changes, with a Consideration of Aphakia. By LOUIS STRICKER, M.D., Cincinnati, O. Pp. 600. 1899.

Dr. Stricker intended originally merely to make a translation of Otto Becker's classical monograph, "Pathologie und Therapie des Linsen Systems," which appeared as a part of the Graefe-Saemisch Handbuch in 1877 and his "Zur Anatomie des gesunden und kranken Linse," which he published in 1884. Although the improved laboratory methods which have come into more general use during the last decade have greatly increased our knowledge in other directions, it is unfortunate that in this particular department of ophthalmology a similar gratifying advance has not been noticed; much, however, has been done and consequently the compiler has seen fit to so enlarge the scope of his work as to include as far as possible what new facts have become known and what new theories have been promulgated in the various countries. The title that has been selected, comprehensive as it is, but inadequately describes the immense amount of subject matter contained within the covers and is likewise inadequate to a just conception of the amount of labor necessarily expended in the preparation of a compilation so extensive, the sources of information being often so remote. Numerous footnotes and a bibliography in chronological order from 1532 to 1895, comprising 3,433 references, help to make the book of inestimable value for purposes of reference. It is a matter of exceeding regret that such excellent results attained at the expenditure of so much time and energy should be so marred by careless proofreading; the errors in spelling, numerous as they are, may easily be eliminated from a future edition, which it is to be hoped will be printed upon better paper and be submitted as a more satisfying example of the art of book-binding.

Clinical Lectures on Mental Diseases. By F. S. CLOUSTON, M.D. (Edin.), F.R.C.P.E., etc. Fifth edition, pp. 727. Philadelphia and New York: Lea Brothers & Co. 1898.

This rarity — an entertaining scientific work — has reached its fifth edition in less than fifteen years, an unusual if not unprecendented achievement for a book on mental disease. Its well-deserved success is in large measure due to the author's vivid and faithful delineation of the disorder in all its varieties. His descriptions and cases make a masterly collection of clinical pictures, unequalled in modern psychiatric literature. His now well-known studies of the influence of development upon the sane and insane mind, which have materially advanced our knowledge of the pathology of insanity, still further enhance the value of this volume.

The present edition is mostly a reprint of the last, the only additions relating to the use of thyroid extract in certain cases of insanity, and to some original pathological work done at the Edinburgh Royal Asylum and the Scotland Asylum's pathological laboratory.

Luke; the Beloved Physician. By J. C. CULBERTSON, M.D., Cincinnati, O. 1899.

It is worth while for the physician occasionally to turn aside from the ultra-professional literature which forms the bulk of physicians' libraries, and to contemplate the lives of those men of early times of whom brief fragmentary sketches constitute our best information.

The beloved physician, whose life forms the subject of this excellent character sketch by Dr. Culbertson, is best known to us by his writings. Of his active skill as a physician or surgeon we have little or no information. As a keen observer and reporter of the exciting events which he witnessed in the first century of the Christian era he had no equal. His deep professional interest is shown by the minuteness and care with which he portrayed the infirmities and the diseases to which the people of those times were subject.

REGULATION OF MASSAGE IN HUNGARY. — The Hungarian Minister of the Interior has issued stringent regulations for the control of massage establishments, etc. Massage treatment in diseases of the sexual and abdominal organs and of the eye may be carried out only by qualified medical men. In all other cases the operator must have the advice and supervision of a qualified medical man. Transgressions of these rules is a misdemeanor punishable, if free from aggravating circumstances, by imprisonment up to fifteen days and a fine not exceeding 100 gulden. — *Medical Magazine.*

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 20, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TETANUS AND FOURTH OF JULY.

THE fact that six deaths have occurred in Boston and twenty-four in New York and vicinity from tetanus, the injury in almost every case being due to toy-pistol wounds received on the Fourth of July, calls attention anew to the barbarous character of the American method of displaying patriotism on that day.

Fireworks have to be exploded in the middle of the dusty road, or in a vacant lot with a dirt surface, in order to avoid littering lawns or setting fire to houses, and the result is that the irresponsible small boy is turned loose with his fellows to spend the day in a grand carnival of dirt, gunpowder, racket and patriotism. By the time he has gotten his hands into a condition of grime superlative even for the small boy, he bethinks himself of the toy pistol which his father has provided him with to cap the climax of the celebration, and in his haste and excitement, handling it with his finger on the trigger and his left palm over the nozzle, fires the blank charge of wadding into the bacillus-laden dirt which smears his palm, and carries it through the skin and palmar fascia in among the tendons and nerves. A bullet would be a safer charge for the cartridge, for it would go clear through. The boy then runs to his mother, who finds that the wound looks trivial (the little puncture in the tense palmar fascia gives no idea of the amount of dirt, wadding and havoc inside), washes the hand, ties a rag around it, and the boy goes on with his play.

The mother may, as, alas, has not infrequently happened, take the child to a doctor, who not remembering the anaërobic nature of the bacillus, and the fibrous strength of the palmar fascia, so well adapted to cover and hide the dirt and wadding, makes a superficial examination, perhaps probes the wound, puts in an antiseptic dressing and sends the child home. The wound apparently does well, there is no swelling or redness, or at most a slight seropurulent discharge.

In four or five days the symptoms of lockjaw set in, the boy is hurried to a hospital, where all too late a quart or so of antitoxin is injected into his vein or his brain, the wound is thoroughly opened up, the wadding and *débris* removed, but the poison has already locked the nervous system in its iron grip, the poor boy's back stiffens and arches, he cries with pain as the convulsions become more frequent, and dies within a few hours of his admission to the hospital.

Now the pity of it is that this whole sad story need never have taken place were it not for the manifestations of carelessness and ignorance at several points. In the first place, even if the Fourth of July must be celebrated, let the parents, however willing to trust their precious offspring to the tender mercies of the dynamite cracker and the toy cannon, remember that the toy pistol with the so-called blank cartridge is more dangerous to their boy himself, at least, if not to the bystanders, than a 32 Colt revolver loaded with ball cartridge, and let them refrain from including it among the dangers to which their liberality and patriotism subject him.

In the second place, let parents and physicians remember that punctured wounds through the palmar fascia must be widely opened and kept open, and cleaned and kept clean. Common atmospheric air will poison what few bacilli the doctor cannot wash away. In other words, tetanus is an eminently preventable disease, and it is some one's fault, either from carelessness or ignorance, when a boy dies of it.

When loose talk is indulged in about an epidemic of tetanus as a result of the number of cases that have occurred since the Fourth of July, it is well to remember that the tetanus bacillus is ommipresent in street and stable dirt and garden mould, and whenever the bacillus is presented, by means of Fourth of July and the toy pistol, with the most favorable conditions for growth and multiplication, he is a fool if he doesn't grow and multiply. If every day were Fourth of July we might expect an epidemic of tetanus, but as that is fortunately not the case there is no reason to fear it.

In regard to the results of the serum treatment, the experience of the last few weeks in Boston has agreed with that of previous years in showing that in the acute cases, namely, those in which the symptoms appeared within ten days of the infection, treatment by antitoxin or any other method was useless. In Boston all the cases occurred within six days and all died. The two cases treated at the Boston City Hospital received large doses, 400 to 500 cubic centimetres by intravenous injection, in spite of which the progress of the disease to a fatal termination was rapid.

As noted in another column, the mortality of the New York cases has been very large. In most of these it is stated that the intracerebral injections were employed.

With regard to the efficacy of the antitoxin treatment, when we consider that recently it was employed in very large amounts and without modifying the mor-

tality of the acute cases, it looks as if we must await some more effective preparation, stronger in antitoxic units, before much can be expected from it.

The fact that the milder cases got well under antitoxin treatment does not prove anything, as these cases got well before antitoxin was employed.

THE TREATMENT OF INEBRIETY.

THOSE who are most actively engaged in work among the poor are agreed that alcohol lies at the basis of most of the degradation and misery which is so apparent in any large city, and is also a menace in our smaller towns. Various efforts have been made to remedy or at least modify the evil by legislative acts, with but doubtful success. Prohibition has failed of its end in great degree, and the restriction of licenses has but slight effect where so many are granted. Moral suasion, valuable as it may be in individual cases, will hardly reach the root of the matter, while human nature remains as it is. It would appear, therefore, that we must, in a measure, accept the situation, and while not relinquishing all legitimate means of combating the evil, should rather direct our attention, as physicians, to the vice of alcoholism as a disease, and provide suitable treatment for its victims. The recognition of this fact has led from time to time to the establishment of asylums for inebriates, in which they may have the restraint, combined with the moral and physical care, which are prerequisites to their cure.

The first institution of this sort in America was opened for patients at Binghamton, N. Y., in 1864; after various vicissitudes, dependent largely upon meddling politics, the institution was converted into an asylum for the insane. In spite of the unfortunate outcome of this earliest attempt at systematic medical treatment of the inebriate, over fifty similar hospitals have since been established in America, of which at least thirty are said to be in active operation at the present time. Our own State Institution at Foxboro is an example of what may be done in the treatment of this diseased and dangerous class in the community.

Wherever civilized man has gone alcohol has apparently been his constant companion, to the detriment of the morals of those savage tribes with whom he has been brought into contact, as well as of himself. We have been much interested in receiving a copy of a bill drawn up by Dr. J. M. Creed, of Sydney, New South Wales, providing for the care, control and treatment of inebriates in that community. The bill has already passed the Legislative Council, and is now ready for presentation to the Legislative Assembly for its concurrence. The document is drawn up in a most comprehensive way, and covers a great variety of details. Its object, in general, is to provide judicial authority over the inebriate class, to the end that they may be properly guarded and cared for during the periods of their irresponsibility. Certain of the more important suggestions of the bill are as follow: A judge or magistrate, on application, and after evidence of a medical practitioner, and on inspection, may make an order as to the control of inebriates. Lower courts may make an order in case of an inebriate frequently convicted of drunkenness. The property of an inebriate may be under the order of a judge or magistrate or court in lunacy. Inebriates are not to leave the Colony of New South Wales. Places where inebriates are under control may be inspected by certain officers, including the inspector-general of the insane. A person supplying an inebriate with intoxicants shall be liable to penalty. The governor may license institutions and may make regulations.

In general, the provisions of the bill are admirable, and may well be studied in detail by those interested in such legislation. While there are, doubtless, certain minor points dependent upon the form of government in New South Wales, which would not apply to our States, nevertheless, the underlying principle must be the same everywhere where inebriety exists. Victims of the alcohol habit, for the protection of themselves, their families, and the community at large, must in an enlightened state of society be treated not as criminals, nor as insane, but as sick, and therefore imperatively needing care, for a longer or shorter period.

Appended to the bill before us is an interview with Dr. Creed, which contains much common sense, clearly stated. Among other things he says:

> I have not slavishly followed previous legislation, as it has not been effective. In most cases elsewhere no action can be taken except on the initiative of the dipsomaniac himself, and but few have the self-reliance or sense of duty to do what is necessary for themselves. To be of real advantage any law must contain provision for action to be taken by some other person, if it is proved necessary, without the previous assent of the victim of intemperance. This is done in ordinary cases of lunacy; why should it not be in the madness of drink? It is hypercritical to object to similar action being taken in both cases. Habitual drunkards no doubt might be certified to as lunatics, but we are reluctant to place this stigma on any one who, if kept from drink, will be sane in a week. I have also taken a new departure by providing that a person may be placed under the charge of an attendant without being confined in an institution. In this way many sad cases might be controlled, in which the sufferers would have to be left to perish without it. . . . The best intellects of our time, which have made the consideration of this most important of all social problems a special study, are unanimous in their opinion that it is simply criminal ignorance to continue to treat drunkeness as a crime, when there are known scientific methods of dealing with it successfully — of curing it absolutely in many cases, as I have been, and am doing, even without the aid which this bill would give, and of preventing continuous outbreaks of the use of healthy substitutes for alcohol at the right time.

It is, no doubt, by such legislation, practiced in a large scale, that substantial reforms are to be accomplished.

MEDICAL NOTES.

IMPRUDENT HOMICIDE. — Dr. Lassellette has just been sentenced, in Paris, to two months' imprisonment for "imprudent homicide." The doctor had operated upon Madame T. for a voluminous fibroma of the uterus; a few hours after the operation the patient died. The autopsy revealed a pair of hemostatic forceps in the cavity of the uterus. — *Philadelphia Medical Journal.*

DR. SCHAEFER CALLED TO EDINBURGH. — Prof. E. A. Schaefer, F.R.S., for fifteen years Jodrell professor of physiology in University College, London, has been elected to the chair of physiology in the University of Edinburgh.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 19, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 37, scarlet fever 24, measles 35, typhoid fever 15.

TETANUS AT THE BOSTON CITY HOSPITAL. — Two cases of tetanus as a result of toy-pistol wounds received on the Fourth of July were treated by the intravenous injections of large amounts, 400 to 500 c. c., of the antitoxic serum of the State Board of Health. Both cases were acute, the incubation periods being five and six days, and both were fatal within twelve hours of admission to the hospital.

BUTLER HOSPITAL FOR THE INSANE. — Dr. G. Alden Blumer, superintendent of the State Hospital for the Insane at Utica, N. Y., has accepted the offer of the superintendency of the Butler Hospital for the Insane, situated near Providence, R. I., to succeed the late Dr. Gorton.

NEW YORK.

INCOMPETENT TREATMENT OF THE SICK; AN ATTEMPT TO PREVENT IT. — A public meeting was held at the Waldorf-Astoria Hotel on July 13th, under the auspices of the Medical and Legal Relief Society, with the praiseworthy object of discussing the proper measures to be taken to put a stop to incompetent treatment of the sick by Christian Scientists and others. Unfortunately, however, the affair turned out to be somewhat of a farce, as there were few prominent medical men or other citizens present, and the Christian Scientists, who were on hand in large numbers, insisted on doing most of the talking. By way of formulation of remedial measures the provisions of a proposed bill by Alderman Opie were read, and these proved to be so impracticable as to be ludicrous. The bill might well be styled a law against giving bad advice, and is of such a nature that it could never be passed, or could never possibly be enforced if it were passed.

STERILIZED MILK FOR BROOKLYN. — Mr. Nathan Strauss, July 10th, began to supply the Borough of Brooklyn daily with one thousand bottles of pasteurized milk, free of charge, from one of his sterilizing plants in Manhattan, the distribution of the milk being made under the direction of the Health Department. A wealthy Brooklyn merchant has now offered to contribute $500 toward a fund to establish a milk-sterilizing plant in the Borough, and it is possible that a plant that was in operation there in 1895, and afterwards abandoned, may be reopened.

BELLEVUE'S NARROW ESCAPE. — By the prompt and energetic action of the resident physicians, nurses and attendants, several of whom were more or less seriously burned about the hands, Bellevue Hospital was saved from a destructive conflagration on the night of July 10th. The fire occurred in the infants' pavilion, where there were at the time about thirty women patients and forty babies, and was occasioned by the overturning of a candle, which set fire to the mosquito netting over one of the children's cribs. The flames spread rapidly from crib to crib, but, fortunately, all the inmates were rescued without any serious accident.

SCARLET FEVER AT WEST POINT. — A slight outbreak of scarlet fever of mild type recently occurred among the cadets at West Point, occasioning a considerable scare and preventing the landing of the senior class of cadets from the U. S. Naval Academy, who had come up the Hudson on the training ship *Annapolis* to pay them a social visit.

DEATH AT THE AGE OF ONE HUNDRED AND TWO. — Mrs. Harriet Byron Townsend, daughter of the late John Seaman, died at Roslyn, L. I., on July 8th, at the authenticated age of one hundred and two years. She was born at Locust Valley, not far from the place of her death, on November 25, 1796. Of her numerous descendants there are living two children, ten grandchildren, fifteen great-grandchildren, and three great-great-grandchildren.

THE LATE DR. FABRICIUS. — Dr. Frederick W. Fabricius, acting assistant surgeon, U. S. A., whose death from yellow fever at Santiago is mentioned in the JOURNAL of July 6th, was until recently a resident of New York, where Dr. H. M. Biggs was his preceptor and special friend. He was only twenty-six years of age, and was graduated from Bellevue Hospital in 1895. Later he was an interne of the Metropolitan Hospital for the Insane.

TETANUS IN NEW YORK. — During the three days July 12th, 13th and 14th no less than nine deaths from tetanus occurred in the city of New York, and ten deaths in places in the immediate vicinity, and it is said that between July 4th and July 16th there were in all twenty-four deaths from this disease in the city and vicinity. In almost every instance the tetanus was the result of a pistol-shot wound of the hand received on the Fourth of July, and nearly all the victims are young lads. The toy pistol is responsible for these deaths, the wad of the blank cartridge penetrating deep into the tissues of the hand, in most in-

stances a very dirty hand. One case of tetanus, however, is reported from Yonkers in which the disease is attributed to the scratching off of a vaccination scab, with the result of producing an ugly sore. This patient on July 15th was said to be improving under tetanus-antitoxin treatment. A considerable proportion of the large number of cases of tetanus which have recently occurred in New York and the neighboring towns have been treated with the serum, in most instances, it is stated, by means of intracerebral injections. The percentage of recoveries cannot be given at present, but a large proportion of the patients died, and it seems probable that in most of them the treatment was not resorted to until too late to afford much hope of a favorable result. Of three cases at the Roosevelt Hospital in which the serum treatment was used, one died and two were reported improved. One patient died at the Harlem Hospital and one at the J. Hood Wright Memorial Hospital. Four cases in Yonkers were reported improved, and of two cases in Passaic, N. J., one died and one was reported improved.

ARMY NOTES.

COST OF SUBSISTENCE FOR SICK SOLDIERS. — The orders issued during the Spanish-American War, allowing a *per diem* of sixty cents for the subsistence of each soldier undergoing hospital treatment have been revoked, and an allowance of forty cents per man from the appropriation for the subsistence of the army has been substituted, the latter sum having been found by experience to be amply sufficient.

THE "RELIEF" DETAINED AT YOKOHAMA. — The hospital ship *Relief*, on her way from Manila to San Francisco, with 250 sick and wounded, has been detained at Yokohama by the heavy storms which have prevailed.

POLICING OF VOLUNTEER CAMPS.— Recent orders relieve volunteer organizations in the home camps of the duty of policing their camp areas. The Quartermaster's Department is now charged with that duty, and is empowered to hire civilian scavengers and purchase the necessary appliances. These scavengers will have charge of the construction of latrines and the disposal of their contents, as well as the removal of all garbage and waste. The necessary disinfectants are to be furnished by the Medical Department. This order has been issued as a result of the recognition of the fact that raw troops are unwilling to properly perform the unpleasant tasks required for the maintenance of a fixed camp in sanitary condition, and manifest a strong tendency to evade the performance of such duties. The same order also amends tactics to the extent that latrines may be located by commanding officers as far from the vicinity of the kitchens as may be necessary, it formerly being prescribed that the company kitchens and latrines should be on the same side of the camp area, and hence in too close relation with each other.

Miscellany.

THE FEMALE NURSE CORPS OF THE ARMY.

A CIRCULAR providing for the organization of a corps of army nurses under the direction of the surgeon-general has recently been issued by the War Department. The corps will consist of chief nurses, nurses and reserve nurses, from which assignments will be made by the surgeon-general to such military hospitals as may contain cases requiring the attention of trained nurses. At each hospital to which nurses are assigned, one of them is to be a chief nurse, but under ordinary conditions not more than two will be assigned to hospitals having less than twenty beds. Women not under contract will not hereafter be permitted to serve as nurses in army hospitals except in an unforeseen emergency, the medical officer in charge of the hospital being required to at once report the fact to the surgeon-general for his action. For appointment, nurses must be qualified physically, mentally and morally; must be graduates of reputable training-schools and have had two years' experience in a hospital, and must also be endorsed by the superintendents of the schools in which they may have been trained or graduated. These provisions may, however, be waived in the case of dietists, immunes to yellow fever and nurses who rendered satisfactory service during the Spanish-American War. Contracts with nurses will be for periods of at least a year, except for immune nurses, who are not required to sign for any definite length of time. Nurses recently accepted are considered as on probation regarding their fitness for army service, and if not found acceptable are to be recommended for annulment of contract by the chief nurses under whom they may have served. Such recommendations, after being suitably endorsed by the medical officer in charge, are to be forwarded to the surgeon-general. The contract of a nurse will not be annulled except for good reason, presented in writing and forwarded the surgeon-general through the chief surgeon. The contracts of nurses serving outside the United States may be annulled by chief surgeons, provided the services of such nurses are no longer required; but nurses on duty in the United States, whose services have been satisfactory, will not be discharged except by order of the surgeon-general. For service in the United States the pay of nurses will be $40 per month; for colonial service $50 per month. Chief nurses receive the same pay as nurses where less than five nurses are constantly serving at a hospital. Where five or more and less than ten are constantly serving, a chief nurse receives $60 per month, while if more than ten nurses are serving together the chief nurse receives $75 per month. Nurses are furnished with transportation, medical attendance, furnished quarters and with one ration in kind. Leaves of absence on pay are not to exceed thirty days in any one year, but while on such leave the nurse receives twenty-five cents per diem in lieu of a ration. While on leave of absence the time consumed in travelling to and from the United States will not be counted. Each nurse must provide the prescribed uniform of blue and white at her own expense.

A certain number of nurses who have rendered at least four months' satisfactory service in the army are to be appointed reserve nurses. Each reserve nurse

is required to sign an agreement to enter active service, when and wherever necessary, and to report to the surgeon-general on the 1st of January and 1st of July of each year, and at other times if required. Reserve nurses are not paid except when on active duty and sign contracts for no definite period. A nurse will be dropped from the reserve list upon reaching the age of forty-five years if she ceases for five years to practise her profession, if she becomes incapacitated for duty by reason of ill-health, or for any other good and sufficient reason.

The nurses' corps is at present under the supervision of Dr. Anita Newcomb McGee, the only woman contract surgeon in the army.

THE SECRET OF SUCCESS IN MEDICINE.

WE learn from an American contemporary that Dr. John E. Harper, in an address on Success in Medicine, delivered at the graduating exercises of the College of Physicians and Surgeons of the University of Illinois, pointed his moral by citing the principles adopted by Sir Henry Holland for the conduct of his professional life. Holland began practice, Dr. Harper informed his hearers, "at the age of twenty-one among the aristocracy of the West End of London, and at the outset made the following two resolutions: (1) That he would never practise more than ten months in any one year, spending the remaining two months in travel and recreation; (2) that he would never allow his practice to exceed fifty thousand pounds per annum." To these rules, we gather, he adhered with admirable resolution for sixty-four years, and it is comforting to know that he "several times collected in one year the amount to which he had limited himself." We fancy that most people will fully agree with Dr. Harper that the secret of success in medicine is to make £50,000 a year. The resolution never to exceed that limit is one that most of us would find no difficulty in keeping; nor would many find such a self-denying ordinance as Sir Henry Holland with such fortitude inflicted on himself at all necessary. Sir Henry's plan of starting in practice "among the aristocracy of the West End of London" is another secret of success that is unfortunately not open to every one. Not a few have to content themselves with the aristocracy of Brixton, or Stepney, or even of Whitechapel, but these haunts of fashion have, of course, the advantage that the practitioner has, perhaps, less difficulty than he might find at the West End of limiting his income to £50,000 a year. To speak seriously, Sir Henry Holland's career is about the last which could be used as showing to ordinary practitioners the way to success in medicine. He had altogether exceptional advantages at the start; he lived at a time when a little knowledge went very much further than it goes now; he was largely used by statesmen as a neutral medium of unofficial communication, and by ladies as a purveyor of gossip — it is not on record that on his paying a professional visit one day he was informed that her ladyship was too ill to see him? Lastly, he did not limit his aspirations in the matter of fees to £50,000, but to £5,000 a year. Even this is a self-limitation which most practitioners do not find it needful to impose upon themselves as a rule of professional life. — *British Medical Journal.*

THE VEILED OPERATOR.

THE bacteriologists have discovered that the beard is without doubt guilty of harboring septic germs. Dr. Hübener, of Breslau, according to the *British Medical Journal*, has experimented on several of his bearded colleagues, passing a slide bearing a film of agar-agar two or three times over and through the beard. Out of 26 cases pyogenic cocci were thus obtained in 11; in 3 the staphylococcus pyogenes aureus in small groups; in 8 the staphylococcus pyogenes albus in great abundance. Experiments were tried by Professor Flügge — a man with a beard standing for ten minutes close over an agar plate without a cover, and then standing for the same time close to another agar plate with his beard covered with a mask of folded muslin. The difference in the number of germs thus obtained was extremely trifling. Nevertheless Hübener[1] believes that he has contrived a more perfect beard guard. A frame of the kind seen in the simpler chloroform masks is covered with sterilized muslin, and held to the face by a metal bar passing over the ears, as in a pair of spectacles. It covers the mouth and nostrils, and some of the muslin hangs below it and is tucked under the beard and fixed with pins to the collar of the operating jacket. Dr. Hübener finds his mask very effective. He repeated Flügge's experiments, and on this occasion the agar plate remained sterile in 6 out of 18 experiments with bearded surgeons. In the remaining 12 he assures us that only a few insignificant "colonies" were obtained. We fear that if this mask be adopted here, certain well-known opponents of antiseptics will laugh at the beards of their colleagues, an act which in the East is considered derogatory. Garré recommends that the operator should not wear a mask, but keep his beard moist in sublimate solution during an operation. This practice, however, is very uncomfortable, spoils the beard, and appears to act imperfectly as a guard against sepsis. Several foreign operators, it would appear, habitually wear beard masks. Theoretically, shaving would seem the safest course if Hübener's earlier experiments indicate a constant condition.

Deaths reported 3,194; under five years of age 1,523; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 841, diarrheal diseases 651, consumption 286, acute lung diseases 202, diphtheria and croup 90, typhoid fever 30, whooping-cough 24, measles 17, cerebro-spinal meningitis 13, scarlet fever 11, erysipelas 3, small-pox 2.

From whooping-cough New York 10, Philadelphia 4, Boston and Nashville 3 each. From cerebro-spinal meningitis New York 4, Boston and Cincinnati 3 each, Baltimore, Providence and Newton 1 each. From measles New York 13, Providence 2, Philadelphia and Washington 1 each. From scarlet fever New York 7, Boston 2, Philadelphia and Baltimore 1 each. From erysipelas New York 3. From small-pox New York and Boston 1 each.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 15, 1899.

L. B. BALDWIN, surgeon, detached from the Key West Naval Station and ordered to hospital, New York, for treatment.

R. G. BRODRICK, passed assistant surgeon, granted sick leave for six months.

R. K. MCCLANAHAN, assistant surgeon, detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Key West Naval Station.

L. L. YOUNG, passed assistant surgeon, sick leave extended three months.

J. M. STEELE, surgeon, detached from duty in connection with recruiting rendezvous at Baltimore, Md., and ordered home to wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 13, 1899.

MCADAM, W. R., assistant surgeon. Granted leave of absence for fourteen days. July 11, 1899.

RAMUS, CARL, assistant surgeon. Relieved from duty at the Cape Charles Quarantine Station and directed to proceed to Havana, Cuba, and report to Surgeon H. R. CARTER, for duty. July 13, 1899.

FOSTER, J. P. C., acting assistant surgeon. Granted leave of absence for thirty days. July 11, 1899.

STEARNS, W. L., hospital steward. Relieved from duty at New York, N. Y. (Stapleton, Staten Island), and directed to report to the medical purveyor, New York City, for duty. July 8, 1899.

ALLEN, G. C., hospital steward. Relieved from duty at Baltimore, Md., and directed to proceed to New York, N. Y., and report to the commanding officer for duty and assignment to quarters. July 8, 1899.

PECK, F. H., hospital steward. Relieved from duty at the Egmont Key Detention Camp and directed to proceed to Baltimore, Md., and report to the commanding officer for duty and assignment to quarters. July 8, 1899.

SOCIETY NOTICE.

THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION. — The Association will hold its ninth annual meeting at Washington, D. C., September 19, 20, 21, 1899.

D. PERCY HICKLING, M.D.,
Chairman Committee of Arrangements.

ERRATUM.

In the number for July 13th, on page 40, second column, line twenty-eight, "macrocytes" should read "microcytes."

RECENT DEATH.

RUSSELL STURGIS, JR., M.D., M.M.S.S., died in Boston, July 17, 1899, aged forty-two years.

BOOKS AND PAMPHLETS RECEIVED.

Hay Fever. By Carolus M. Cobb, M.D., Lynn, Mass. Reprint. 1899.

Infant Mortality in Massachusetts. By Samuel W. Abbott, M.D. Reprint. 1898.

Self Examinations for Medical Students. Philadelphia: P. Blakiston, Son & Co. 1899.

Signs and Tests of Death. By Justin Herold, A.M., M.D., New York. Reprint. 1899.

Modern Possibilities in Chronic Catarrhal Deafness. By Sargent F. Snow, M.D., Syracuse. Reprint. 1898.

White Dandy, or Master and I: A Horse's Story. By Velma Caldwell Melville. New York: J. S. Ogilvie Publishing Co. 1898.

Annual Reports of the President and the Treasurer of Harvard College, 1897-98. Cambridge: Published by the University. 1899.

Transactions of the Louisiana State Medical Society at its Nineteenth Annual Session, held at New Orleans, La., May 10, 11, 12, 1898. New Orleans. 1899.

On the Use of the Valeriantes of Creosote and Guaiacol in the Treatment of Pulmonary Tuberculosis. By A. B. Briggs, M.D., Ashaway, R. I. Reprint. 1899.

The Importance of Blood Examinations in Reference to General Anæsthetization and Operative Procedures. By Hamilton Fish, M.D., Ouray, Col. Reprint. 1899.

Electro-hæmostasis in Operative Surgery. By Alexander J. C. Skene, M.D., LL.D., Professor of Gynecology in the Long Island College Hospital, N. Y., etc. New York: D. Appleton & Co. 1899.

Peripheral Nerve Transplantation, with the Report of a Case in which the Sciatics of a Dog were Transplanted Successfully between the Severed Ends of the Median and Ulnar Nerves of a Man. By Reuben Peterson, M.D., Chicago. Reprint. 1899.

Materia Medica and Therapeutics: An Introduction to the Rational Treatment of Disease. By J. Mitchell Bruce, M.A. (Aberd.), M.D. (Lond.), Fellow of the Royal College of Physicians of London, etc. Philadelphia: Lea Brothers & Co. 1899.

Laboratory Work in Bacteriology. By Frederick G. Novy, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry, University of Michigan. Second edition, revised and enlarged, with frontispiece and 76 illustrations. Ann Arbor: George Wahr. 1899.

Chronic Appendicitis the Chief Symptom and Most Important Complication of Movable Right Kidney. The Relations of Movable Kidney and Appendicitis to Each Other and to the Practice of Modern Gynecology. Chronic Nephritis Affecting a Movable Kidney as an Indication for Nephropexy. The Hernia Guarantee and the Minimum of Confinement after Operations for Appendicitis with and without Pus. By George M. Edebohls, A.M., M.D., New York. Reprints. 1899.

Address.

NOT THE DISEASE ONLY, BUT ALSO THE MAN.[1]

THE SHATTUCK LECTURE.

BY JAMES J. PUTNAM, M. D., BOSTON.

(Concluded from No. 3, p. 57.)

EVERY thinking person is aware that our minds work under many masters; we might designate them as our "silent partners." Under normal conditions we have reason to congratulate ourselves at the useful division of labor which this arrangement secures; but when the mental harmony is broken by disease, these masters of the mind jostle and trip each other in their efforts to restore the balance, and then we feel the sort of dismay, the sense of alteration of ourselves, such as in old days was called possession by the devil. The acts that we do are only partly the acts of our personal wills: some of them seem inspired and even performed by a power which is more or less foreign, yet which we feel bound to obey. So Tennyson's sailor boy, who must and will run away to sea, says:

> "My mother clings about my neck,
> My sisters crying, 'stay for shame';
> My father raves of death and wreck,
> They are all to blame, they are all to blame.
>
> God help me, save I take my part
> Of danger on the roaring sea,
> A devil rises in my heart
> Far worse than any death to me."

Or, as the writer of the charming Harvard ballad puts it:

> "Within my earthly temple there's a crowd;
> There's one of us that's humble, one that's proud;
> There's one that's broken-hearted at his sins,
> And one that, unrepentant, sits and grins;
> There's one that loves his neighbor as himself,
> And one that cares for naught but fame and pelf.
> From much corroding care should I be free,
> If once I could determine which is me."[2]

We have not the right, even where we have the wish, to deny our responsibility for the acts of these hidden forces of the mind, and it is a high function of education to enable us to understand and to control them; to make the desirable "me" prevail.

And thus queerly constructed, and perhaps with the demon of distrust looking through his eyes and speaking a language which his words vainly strive to contradict, the patient comes to the doctor, carrying his burden of morbid habits, as Christian, in "Pilgrim's Progress," carried the burden of his sins, seeking for explanation and relief. How shall he be met?

The answer instinctively suggests itself: by some sort of treatment akin to "hypnotic suggestion." This name excites great prejudice in many minds, and I should be glad to have it forgotten until the principles on which such treatment rests shall have been indicated, and the fact made evident that the methods designated differ only in degree from other modes of influence such as every physician uses in his daily practice and every person of strong character in the contacts of daily life. The analogies that suggest themselves in these directions are, in fact, so striking, that there is risk of going too far toward making out the hypnotic method to be an affair of everyday occurrence. One often hears the influence which society exerts over its members spoken of as "hypnotic," and it is quite as justifiable, and more to our purpose, to extend the conception so as to cover the case of a hypochondriacal patient whose judgment and reason have been captured by a morbid habit or a delusion of disease. There are times when we all become unusually impressionable to external influences or to the promptings of our own instincts; and it is clear that this is made possible by the withdrawal of the critical and questioning faculty that stands like a Cerberus at the door of the mind and is the enemy of all impressionability except of its own choosing. It is by no means to be assumed that the person thus altered is necessarily reduced to a lower plane. We make ourselves voluntarily more impressionable and less critical for the purpose of listening better to the whisper of our genius or our conscience, or to the whisper of one such voice chosen out of many:

> "Though love repine and reason chafe,
> There came a voice without reply,—
> 'Tis man's perdition to be safe,
> When for the truth he ought to die.'"

Even the means by which the impressionability of health is voluntarily secured sometimes present a striking resemblance in detail to those which are used for the purposes of hypnotic suggestion. Take, for instance, the case of a person who is striving to recall some name or fact. The whole substance of his effort consists in eliminating everything that stands in the way of complete passivity. He sits fixedly gazing at some object, yet taking no heed of what he sees; he hears the ticking of the clock with unusual intensity, but the sound does not reach beyond the ear, and serves only as a means to keep him from entertaining any stronger interest that might prevent his catching the first glimpse of the real object of his desire, if, by chance, impelled by the hidden forces to whose influence he submits himself, it should drift across the field of his mental vision.

I need not pursue these analogies further in order to convince you that a patient staggering under a tormenting and dominating habit has no reason to feel humiliated when he yields to an influence so familiar as that which I have indicated, in order to make himself impressionable to the words of encouragement from the physician in whom he has confidence, and who is striving by these means to reveal to him another and truer picture of himself than that with which in his delusion he has been so long familiar. And this applies also to the child, impressionable by nature both to evil and to good, and sometimes a victim to tricks of bodily and mental habit which can be removed only by deep-reaching influences of these sorts, if even then.

A sweeping condemnation is often brought against the use of hypnotic suggestion, based on the assumption that it involves the subjection of the will of the patient to that of the doctor. But this same sort of influence is exerted daily in the schoolroom, in social intercourse, and most of all in the army, and the results are good or bad according to the obvious intention of the method, and to the intelligence or ignorance, the high-mindedness or low-mindedness of the person by whom it is brought to bear. The physician who domineers over his patient, or makes him a slave to needless rules, can weaken his independence with-

[1] Delivered before the Massachusetts Medical Society, June 13, 1899.

[2] E. S. Martin: Sly Ballads in Harvard China.

out hypnotic suggestion; while he who is bent on strengthening the patient's will can and must call special methods, analogous to those of hypnotic suggestion, to his aid. Nevertheless, the final aim of the doctor, as Madame De Staël said of the legislator, should be to make himself unnecessary, and we may add, in company with the sturdy Sir James Paget, to make, if it is warrantable, even his rules unnecessary.

For the attainment of the ends that I have indicated the patient must be taught to let his critical instinct and his will lie passive at first, while the new set of motive-impulses is being presented, but finally to use them for reinforcing the new mental attitude which they could not have created alone. The part thus assigned to the will is not a wholly negative one, and the imputation that the patient grows strong solely through another's effort is only correct if the treatment stops short of the final stage. In fact, the whole treatment, from first to last, and at every stage, involves the patient's consent and co-operation. This passivity or "consent," whichever one may call it, of the critical instinct and the will may be induced in many ways. The teacher secures it when he exerts over his pupil the fascination of his personal influence for the purpose of interesting him in his tasks; the physician secures it when he induces his patient to sit or lie quietly with muscles relaxed and senses engrossed, so that he shall listen without inclination to comment on what is said, or shall allow his own sense of encouragement and hopefulness to take deeper root. If, after such treatment, the patient comes and says: "I heard what you said, but cannot now repeat it," and if, thereafter, his act shows the reappearance of the newly-suggested impulse in the form of an apparently spontaneous product of the patient's thought, the most desirable result will have been attained. This kind of treatment may be called "hypnotic suggestion" if one will, but the prejudices that this word used to excite would never have arisen if such therapeutic measures as these had alone been in question.

It would, however, be disloyal not to recognize that even the experimental uses of hypnotic suggestion, objectionable as in some respects they are, have been of high value to medicine. It is to the studies made possible by hypnotic methods that we owe much of our present familiarity with that part of the mental life that lies beyond the direct reach of our personal attention, and if to this we add the service that treatment involving profound hypnotic influence has rendered in many cases of serious and otherwise incurable disorders we have abundant reason to be grateful for Braid's and Liébault's discoveries. Nevertheless, it has, fortunately, been found that the actual induction of the hypnotic sleep is far less often necessary, so far as therapeutic purposes are concerned, than was formerly believed. The results effected through it have given the hint that simpler methods might suffice, and so have inspired with new power the physician's confident assurance of improvement or recovery that gets the name of "waking suggestion." It is the patient's misfortune if this assurance does not reflect the most thorough diagnosis that science can command and the most hopeful prognosis that the conditions, *taken at their best*, can justify. Unfortunately, it sometimes happens that the very scientific training which justifies the physician's dignified position of authority in the community acts to prevent him from "taking at their best" the influences that make for a good prognosis. The capacity, one might also say the genius, for improvement which the patient often shows is apt to be underrated, just because it is so mysterious, so undefinable, and so wayward. Both physician and patient need to realize more fully that the latter has, to a considerable degree, the germs of a real power of control over his bodily and mental states, provided his personality is conceived of in a sufficiently broad sense.

Whatever be the method by which the influence is secured, the treatment of these diseases of association and habit must follow one of two familiar courses. The first is that of eliminating from the mind the troublesome and recurrent impulse or habit; the second, that of introducing another impulse incompatible with the former and tending therefore to its exclusion. Both of these attempts are made in education of every sort, but it is safe to say that the latter is by far the more successful of the two, and is in fact the one which mainly does the work even when it is not ostensibly employed. It is wiser to build up than to pull down, to induce virtue than to eliminate vice, to get rid of morbid thoughts by supplanting them with others that are better, or to utilize them as materials for growth rather than to conduct a campaign against them. The restoration of motion is the essential factor. The swiftly-flowing river will quickly absorb the muddy brooks that enter at its sides. That is, to say the least, the "Western" as distinguished from the "Oriental" mode of progress. It is true that great therapeutic advantages have seemed from time to time to have been gained by seeking out and casting out a painful or bitter experience which had been germinating, perhaps for years, in the mind, hidden from view except in its morbid manifestations, which took the form of hysterical outbreaks, moods of depression, disordered sleep and other phenomena of like character. Several remarkable series of cases[10] have been reported where such ideas have apparently been traced to their lair and then exterminated, and with them the complex organization of morbid ideas and emotions of which they formed the centre. I believe, however, that this explanation of the therapeutic successes which have unquestionably been achieved in such cases is not necessarily the correct one. One may readily believe that if a patient could be brought to give his tacit consent to any theory of the cause of his troubles which the ingenuity of the physician might suggest, he would gain new hope and receive an effective impulse toward recovery, even if the theory which was offered him was not the true one. The main point is, I believe, to secure a nucleus for a new set of associations which shall be exclusive of the old ones. The patient is to be taught to push ahead in the direction of health and activity as one pushes his way through a thick forest, regardless of the scratches and bruises to which he is exposed on the way, and it does not greatly matter whether the path of escape is or is not identical with that which was followed when the way was first lost, except in so far as that it is important to gain the patient's ready acceptance of the path actually proposed.

Unfortunately, even the much vaunted hypnotic suggestion often fails to work; or if the new suggestion seems at first successful the morbid habit may in

[10] See contributions by Dr. Russell Sturgis on the Use of Hypnotism to the First Degree, in the New York Record, Feb. 17, 1894; also Ibid, 1899. The earlier publications by Janet, Breuer and Freud, and others should be noted in this connection, and also Loewenfeld's excellent criticism in his Psychotherapie.

the end settle heavily back again. Is "Philip drunk" or "Philip sober" really the stronger and more consistent character? This is a question which the doctor often has to ask himself and to which, perhaps, it is only by trial that he can find the answer. Fortunately, in the memory of Philip sober there may be groups of half-forgotten experiences[11] dating back perhaps to the days of his youth, and capable of forming, by their union with the new impulse, a temperament sympathetic with the better course, and thus he may be enabled to prevail. One may try to express such conditions in terms of cerebral anatomy and physiology, but it is doubtful whether, in the present state of our knowledge, a clearer conception of the process would thereby be gained.

Fortunately for the educational outlook, the evidence has begun to accumulate that a morbid inheritance is not the inevitably crushing and baneful thing that it has been thought. We come into the world, each one a being of limited capacity but in other respects free to become what circumstances make us, and responsible, to the extent of our capacity, for our lot. We bring no ticket-of-leave which stamps us as drunkards or maniacs on probation, but we do bear, in the histories of our ancestors, a certificate that hints by what efforts and by what avoidances we can make ourselves reasonable successes in our respective lines. There is no original sin, and not even, as it seems to me, original propensity, but only original capacity and original limitation, and even limitation is only another name for latent capacity.

A highly interesting side-light is thrown on the discussion between these two doctrines — the fatalistic doctrine of propensity and predestination, and the more hopeful doctrine of plasticity limited only through capacity — by the evidence adduced in a somewhat similar discussion which has been going on among the embryologists. What is it that gives our bodies their definite and ever recurrent form? Do the nerves as they pass from their centres of growth to their destination in the skin and in the muscles bend and twine to find their passage in obedience to some inherent tendency of growth, or does each cell-process start out not only ignorant of its future but without a positively defined future, and make its way in obedience to mechanical laws of least resistance and simple laws of growth, just as a rootlet makes its way amongst the stones in its seemingly inspired search for the distant water? If I understand aright the teaching of the present day, the latter is the case. This teaching does not aim to rob heredity of its powers, but, in so far as it is applicable to the problems of mental growth, it does glorify the influence of education in making us what we are. The child of the drunkard does not inherit drunkenness, but he does inherit a defective brain, a brain liable to go wrong perhaps in many ways but reclaimable to a considerable extent through education; just as the child of the tuberculous parent does not inherit tuberculosis but the soil on which it may develop. The difference between these two doctrines is more than an academic quibble. It is one of vital tendency.

The cases that I have thus far had in mind have been of relatively curable sorts, either because the patients had traditions of good health to look back upon, or because it was assumed to be possible to cast out some special fixed idea, or habit, or delusion of illness, which had arisen in consequence of some more or less accidental experience, but still lay loosely attached in the mind, or, at any rate, had not become, through the bonds of association, an integral part of the great body of ideas and feelings on which the patient's mental life revolved. But these disorders arise more readily, strike their roots wider and deeper, and keep a more tenacious hold if there is a native defect in the mechanism of the nervous system such as we see in that great class of cases which for convenience's sake may be grouped as *constitutional neurasthenias*. With such patients the problem of treatment is often not so much to rid them wholly of the consciousness of their symptoms as to aid them to look through and beyond their troubles, and eventually in some degree to ignore them, as one learns to ignore a defect in vision.

If patients with this sort of illness are often plagues to themselves they are no less a source of sighs and groans to their doctors and their friends. Yet they are among the best and keenest people in every community, and it may even be said that it is their doctors and friends who are in a measure responsible for keeping them what they are,— at least in the sense that salt was defined by the small boy as that which made potatoes taste so bad when there wasn't any on. In other words, they would be better off if we knew better how to appreciate and to treat them. Liable to fatigue, and unable to accomplish as much as their robuster neighbors, such patients become keenly alive to their failures, and are apt to fall into mental habits marked by baffled reason, morbid self-consciousness, and balking will. Beginning by suspecting and hesitating, they often end by ceasing to act. The limitations set by the original "weakness" are of trifling consequence as compared with these secondary and needless incrustations, framed from false premises by the patients' inexorable logic. But the balking will, like the balking horse, can often be trained to work again; the obstacles that seemed so invincible when tangled into a web made up of the memory of past failures and fears can often be overcome if taken piece by piece.

Fortunately, it is by no means every neurasthenic patient whose case takes the unfavorable course that I have indicated. There are many persons, weak in body but unconquerable in spirit, who keep themselves free from this entangling web of troubles. They make unnecessary the therapeutic suggestions of the physician by accepting their limitations as indications for casting about to decide on their best course for the future and best means of usefulness for the present, and striving to regard the tasks imposed by illness in the same light as the tasks imposed by health. Such persons give new meaning to the fine words that Tennyson puts into the mouth of the aged Ulysses:

> "Tho' much is taken, much abides; and tho'
> We are not now that strength which in old days
> Moved earth and heaven; that which we are, we are;
> One equal temper of heroic hearts,
> Made weak by time and fate, but strong in will
> To strive, to seek, to find, and not to yield."

The problem for the physician in dealing with patients to whom such a course as this does not come instinctively is to use all the means that may lead to its adoption. If there is any slender thread of interest or enthusiasm or even of fanaticism in their composition

[11] See Dr. Mary Putnam Jacobi's paper, A Suggestion in regard to Suggestive Therapeutics, in the New York Medical Journal for April 9, 1898.

it should be recognized and encouraged. And, happily, the slender thread is often enough. It has not the all-embracing power of the large and warm temperament of hopefulness, but what is lacking in massiveness may in a measure be made up for by intensity. The almost fierce glow of energy and fortitude seen in some of the frail-bodied New England women portrayed by Miss Wilkins gives a good illustration of this principle.

Neurasthenic patients cannot, as a rule, be expected to overcome their troubles alone. We say to them, "make an effort of the will and do this or that," but the will cannot create situations, but only choose between them, and although it is true that a better choice usually exists than that which the patient makes, yet to see this and to choose correctly is a task of no little difficulty. Such a patient is compelled at each step to compare the act which he wishes to accomplish with that which he wishes to avoid, and so the latter is presented afresh with all its imperative fascination, as a card is forced on a novice by a skilful player. It is the physician's part to present a new alternative for the reason to adopt and the will to act upon. When such patients clearly understand that, with patience and the cultivation of a dogged indifference to symptoms which are unimportant though annoying, they can learn to note and to accentuate their powers of accomplishment and enjoyment, the ground is already cleared for the action of food and tonics, recreation and active work.

An element of special encouragement and mental stimulation in particular directions may be made to accompany treatments designed ostensibly to fulfil other needs. The famous so-called "rest cure," which the genius of Weir Mitchell devised, owes the remarkable success which it exhibits in able hands less to rest and food in themselves than to the mental influences that go with the isolation, the scrupulous precautions that leave no excuse for indigestion or fatigue, the obvious confidence of the doctor and the nurse, and the contagion of recovery such as permeates every successful hospital. All these changes in the patient's surroundings are often, from the point of view of mental influence, more effective than a journey to Europe, though even as regards the latter the familiar lines:

> "Cœlum non animam mutant,
> Qui trans mare currunt."
> (They change their skies but not themselves,
> That cross the seas.)

are, luckily, not always true.

Many a doctor has tried the rest treatment and has failed, because he did not follow exactly Dr. Mitchell's rules, not realizing that in omitting certain "surely unessential" details he was leaving out the very heart of the mystery. On the other hand, I fully agree with Dr. Prince [13] that results similar to those accomplished through the agency of the "rest cure" may often be obtained through pure mental stimulation and education.

Take next the question of physical exercise, which may stand as a type of a whole class of treatments. You recommend it for your neurasthenic patient, but to what end? Do you wish to toughen his muscles, to help his digestion, to strengthen his heart? Or is it in fact recommended for the sake of introducing the leaven of energy, in the hope that it may finally infect his whole mental life? If such is your desire, five minutes of sharp exhilarating work or play will do what hours of chest-weights would fail to accomplish. Perhaps you may even start a love for the study of physical development and thus give a new impulse to an invalid life. It may be as when a boy, dull at his books and drifting into general incompetency, has the good fortune to meet some one who discovers that he is a genius at whittling, and who by encouraging him in this accomplishment gives him a chance which will in the end transform him not only into a good mechanic but into a man of first-rate, all-round capacity. And so, too,[13] relaxation of body may be employed to teach relaxation of mind. On the same principle, a soothing treatment by water or electricity may help to give the genius of sleep a better chance to control the currents of the mind.

It is worth while to note what a needless weight of sombre forebodings is often carried by a *word* or *name* to the patient's anxious mind. To feel "tired" may be bad enough at the best, but it makes a world of difference whether one accustoms himself to take the term as meaning the fatigue of a person who expects in due time to be rested, or as a bottomless pit of exhaustion, demanding sighs and groans. It is true, as Dr. James says,[14] that the drunkard's reform often dates from the day that he gives himself the unsavory name, it is equally true that needlessly alarming symptoms can often be unmasked on the reversed principle; as a legal friend of the writer once, in court, robbed an "excoriated tibia" of its terrors by rendering it as "barked shin"

Happy is the neurasthenic patient who has a sense of humor or a liking for philosophy, so that he can get a certain satisfaction from externalizing his troubles, as William Blake painted his visions and Bunyan put his into the Valley of the Shadow of Death. To learn to recall the good days on the bad days; to remember that the University of Leyden was founded during the starvation of the great siege, and to realize that limitations are also finger-posts to new sorts of progress, infuses a sense of triumph into one's efforts toward the self-forgetfulness of effective life. Many patients think that they are not gaining, because the signs of improvement are less obvious to them than the signs of failure. The latter stand out in painful isolation; the former lose their own identity in augmenting the general efficiency, just as the stippled spots of paint on the impressionist's landscape blend into a glow of color. Fortunately, however, the test of successful work and the sense of comfort that accompanies it usually tell the truer story, and the physician can powerfully intervene as an interpreter.

Neurasthenic patients are often led, partly by native temperament, partly through the circumstances of their illness, to seek philosophic views of life, and indeed without some familiarity with them even the buoyant satisfaction that successful work brings to the healthy mind leaves something to be desired.

The inspiring doctrine of individuality, with which the pages of Emerson are full, that heightens one's interest in the novelties which the light coming through one's own window, the touchstone of one's own genius, can alone reveal; the reassuring belief that urges us to "live ever in a new day," and forbids us to drag

[13] Educational Treatment of Neurasthenia: Boston Medical and Surgical Journal, 1898.

[13] As Miss Annie Payson Call has so well explained.

[14] Talks to Teachers.

around the "corpse of our memories" of evil; the great doctrine of "service," which presents only another aspect of the principle that if a man consistently follows the lead of his own best instincts he is sure to find that his interests are at one with those of an ever-widening community; such principles as these are like so many watch-fires, blazing up from the hill-tops into the darkness of the night.

In conclusion, I would say, as I said in opening, that every physician is an educator, whether he will or no, and should study to be a good one. He works of necessity with a threefold object in view: to cure his patient; to leave him better able to cure himself another time; and to establish systems of treatment that shall reflect sound and liberal views. He must of necessity come into close personal contact with his patient, and may therefore, through the powerful influence of his own personality, make him narrow or suspicious, or unduly dependent on rules and mysteries; or, on the other hand, more reasonable, more self-reliant, more liberal, a firmer believer in his own genius, and the supporter of simpler creeds. The opportunity for usefulness is an enormous one; for I hold that to rid a patient of a tormenting delusion and to increase his power of resistance against debasing habits and thoughts is quite the equivalent of a successful operation for a painful disease, and needs as much skill and preparation. It is to the opportunities and responsibilities of this task, which should not be evaded, that I have tried to call your attention.

The physician, too, must call the community to his aid; for many of these disorders start in the imitation of inferior social customs and in the acceptance of narrow social traditions, and we may confidently hope that they can be eliminated in part through changes in public feeling such as an intelligent doctor may help to set on foot. The community is neither intentionally ignorant nor intentionally heartless. It adopts the easiest and nearest opinion, and is readily open to change. We gather at our annual meeting to gain strength from the contact with each other, as Antæus from his Mother Earth; let us separate again, each to be a centre for the spread of knowledge not only of those forces whose effects are to be measured by the microscope and the chemist's tests, but of those also which no chemist can estimate, but which may, nevertheless, work upheavals in social sentiment, as the water which trickles into the crevices of the rock may one day freeze and burst it asunder.[15]

Original Article.

PERITONSILLAR ABSCESS.[1]

BY FREDERIC C. COBB, M.D., BOSTON.

PERITONSILLAR abscess may be defined as a phlegmonous inflammation occurring in the tissue surrounding the tonsil. Its best-known synonyms are quinsy and acute phlegmonous tonsillitis. Widely different views as to its causation are given by various authors. Bosworth and Lenox-Brown are firm believers in its rheumatic origin, while others believe it to be due to the entrance of germs into the peritonsillar tissue resulting from acute tonsillitis. In the records of my cases, the question of rheumatism could not always be decided, but the results are as follow: Those having no history of rheumatism numbered 18, while those in which the history was doubtful were 19, and those having a clear rheumatic history were seven. As to the question of whether the quinsy was due to infection from the tonsil, we can only judge by examination of its condition at the time of the peritonsillar inflammation. It must be remembered that even when tonsillitis precedes an attack, the tonsil may have cleared up when examined four or five days later, the time when peritonsillar cases usually present themselves for examination. In 24 of my cases there was no distinct lesion of the tonsil recorded, while in 18 the tonsil was clearly pathological, being either swollen or covered with exudation, while in seven only could no lesions be found. As to age, the youngest of these cases was seven years old, while the oldest was fifty-five; the largest number of cases, or 29, were between the ages of ten and thirty, those occurring between thirty and forty being only five, those below ten years, but three.

Pathology.— The pathology of quinsy does not differ from that of any pus formation in cellular tissue elsewhere, the especial point of interest being found only in the study of its anatomical relations. Most authors speak of the inflammation as localized in the tissue immediately surrounding the tonsil. Chiari alone suggests that pus is to be found in the pharyngomaxillary space. This space is well described by Zuckerkandl in his paper on the "Relation of the Tonsil to the Great Vessels." The pathology of peritonsillar abscess can be understood only by an anatomical study of the tissues surrounding the tonsil. The tonsil is bounded in front by the palatoglossus or anterior pillar, behind by the palatopharyngeus or posterior pillar, some of the fibres of which pass around it in such a way as to form a kind of sling. Its inner side is free, while on the outer it is in relation with the amygdaloglossus and the styloglossus, which are small muscles, and some fibres of the posterior pillar or palatopharyngeal, as heretofore mentioned. Directly outside of these few small fibres we find a hard fibrous-tissue wall about one millimetre in thickness from which fibrous septa run into the tonsil. On removing this tissue we come upon the superior constrictor of the pharynx, a muscle of much greater size than those just mentioned, and, continuing outwards, upon the buccopharyngeal fascia which lines its external surface. This fascia forms the inner wall of the pharyngomaxillary space, a cavity of considerable size when dilated. This space is described by Linhardt as a cavity filled with connective tissue and fat between the side wall of the constrictor, the internal pterygoid and the upper vertebræ, containing in its posterior part the great vessels of the neck. It was left to Zuckerkandl to show that this space was divided into two smaller ones by the styloglossus and stylopharyngeus muscles. These form a partition wall, back of which, in the rear of the space and behind and to the outside of the tonsil, lie the great vessels of the neck. The extent and appearance of this space is well shown by a cross-section of the head at the level of the teeth

[1] Read before the American Laryngological Association, May 22, 1899.

[15] I am aware that an account of "mental therapeutics" could make no claim to completeness, even in outline, if it did not discuss the limits of action of this agency. Nevertheless, this part of the subject is too large to handle briefly, and too important to dismiss summarily. I therefore leave it for another occasion, and content myself with a reference to the treatment of these affections which the general practitioner must treat on the lines here indicated, if he wishes for success.

and the lower jaw taken from Testut's "Anatomy" (Fig. 1). It will be seen that the space extends nearly to the angle of the jaw by a prolongation between the pterygoid and the superior constrictor muscle. This explains why abscesses sometimes break near the wisdom teeth. The walling off of the posterior portion by the muscles spoken of is not, however, so clear in the diagram as it is on dissection of the parts.

In order to assure myself that this partition was efficient, and also to trace the direction of least resistance to the passage of fluid in this space, I injected the cadaver, through the tonsil, with wax, passing the point of the needle well through the constrictor muscle into the pharyngomaxillary space. The result was gratifying, the injection passing in quite easily and giving the palate a very characteristic appearance of peritonsillar swelling. After allowing the wax to harden, a cross-section of the part was made just below the hard palate, and the route of the injection traced (see Fig. 2, with accompanying diagram, Fig. 3). It was found to have filled the space extending along the lines spoken of in Testut's diagram, toward the region of the teeth anteriorly as well as into the soft palate, or as far as its junction with the hard palate. Figure 2 corresponds with Figure 3, the dark spaces showing clearly, after the wax has been removed, the pharyngomaxillary fossa, the muscles and vessels of which are outlined. The injection did not extend into the space occupied by the great vessels in the rear of the pharyngomaxillary space, but it was stopped by the diaphragm formed by the styloglossus and the stylopharyngeus muscles. On removing the wax from the pharyngomaxillary space, a deep cavity was found extending not only beneath the tonsil but also above into the soft palate. The distended cavity could have contained three or four drachms of fluid easily. The presence of pus in this space would, it seems to me, explain the usual phenomena of peritonsillar abscess. In order to reach the posterior pillar, pus must force its way either through the soft palate from the upper part of the space and so infiltrate the pillar, or it may pass through the superior constrictor above or behind the tonsil directly into the pillar. The portion of the constrictor at which least anatomical obstruction was found appeared to be just above and below the tonsil, between the anterior and posterior pillars. It is to be noted that the fibres of the anterior pillar and those of the constrictor cross each other at an angle, a fact which may explain the occasionally ineffectual results of puncture of the abscess.

It is not of course claimed that all abscesses arise in this space, since removal of the tonsil sometimes exposes an abscess cavity at its base, but it is claimed that many cases of peritonsillar abscess owe their clinical appearance to the accumulation of pus in the pharyngomaxillary space forcing both the tonsil and peritonsillar tissues forward and inward. If pus were situated between the tonsil and the pillars, it would force the pillars outward and the tonsil inward at the same time, yet we usually find the tonsil occupying its normal relation to the pillars, the whole being, as I have said, pushed inward and forward. The very large amount of pus often found in these abscesses is, it seems to me, too great to be accounted for by its presence in the small areolar space at the base of the tonsil. Assuming that this space is the seat of the pus formation, it would seem natural that it should sometimes force its way backward among the great vessels in the neck in spite of the septum already described. Clinically such cases have been recorded. Bosworth cites a case reported by Reid[1] in which pus burrowed along the vessels into the mediastinum; another by Kiemann[2]; and a third by Velpeau[3] and Beraud, in all of which the pus had burrowed along the vessels into the cellular tissue of the neck, sometimes extending into the mediastinum, in two of the cases causing a pleurisy.

Symptoms. — The symptoms of peritonsillar inflammation observed in my cases have not differed from the clinical picture. Patients usually presented themselves between the third and sixth day, with great increase of saliva and complaining of great, usually unilateral, pain on swallowing. The voice was dry and thick, the temperature always considerably above the normal. The duration of most of the unpunctured cases was seven days, but occasionally one lasting ten days or even two weeks was encountered. The soreness, however, from which the history of the beginning of the peritonsillitis was derived may have dated from an acute tonsillitis preceding the abscess formation. In one case pain existed before any peritonsillar swelling appeared, and it was not until two days after that the peritonsillar swelling became noticeable. In none of the cases were there symptoms of the extension of the swelling beyond the fauces.

Treatment. — Almost all the cases presenting themselves for treatment were so far advanced that it seemed hopeless to try to abort the abscess by salicylates, aconite or guaiac. Indeed, early experience with acute peritonsillitis had not given me much encouragement to pursue this treatment. The main and most important question seemed to be, when and where to open the abscess. The usual point selected was in the median line above the tonsil between the root of the uvula and the gingivopalatal fold. When incision was made here it often happened, even after the most generous opening, that the wound closed, and that twenty-four or thirty-six hours later the abscess ruptured elsewhere. In such cases pus was not seen to ooze from the location of the puncture, but either the opening could not be found or pus exuded from between the pillars, usually above the tonsil. All the cases, of course, could not be followed, but the average date of relief in the cases punctured was almost exactly that of those unpunctured, which was a fraction under seven days. The closure of the punctured cases seems to me to be due to the differing direction of the muscle fibres of anterior pillar and superior constrictor. When the knife passed into the wound these layers were in abnormal relations to each other on account of the tension caused by the gagging movements of the throat; when the throat again became quiet the muscles assumed their normal relation, the openings sliding over each other so as to close the vent made by the knife. It was noticed that wherever a yellow spot in the palate seemed to indicate the pointing of the abscess relief after incision was instant and persistent. The explanation of this, it seems to me, is that the muscles were here glued together by the inflammatory exudation in such a way as to prevent the riding-over motion spoken of. By far the most usual point of passage of pus was found to be between the pillars of the fauces above the tonsil, suggesting that to puncture in this locality would

Transverse Section of the Head slightly below the Hard Palate.

be following nature's indication. The danger from hemorrhage of such a puncture would not be great, since the large vessels lie in a plane posterior to that of the posterior pillar. The knife used should be a right-angled one in order to avoid passing this plane.

Summary.—The whole number of cases examined was 44.

(1) No causative relation could be proved to exist between rheumatism and peritonsillar abscess.

(2) An acute inflammatory condition to the tonsil was found to exist in a sufficient number of cases to suggest that it may be the cause of the infection to the peritonsillar tissue.

(3) A study of the pharyngomaxillary space shows: (*a*) that its injection with wax on the cadaver may produce an appearance similar to the peritonsillar abscess as seen clinically; (*b*) that its distance from the surface of the palate may account for the depth of the puncture often needed in order to obtain pus; (*c*) that the cross action of the muscles covering the space seems a sufficient reason for the closure of punctures made into it; (*d*) that the supratonsillar fossa and the infratonsillar space offer the surface for puncture most free from anatomical obstruction; (*e*) that puncture anterior to a plane passing through the posterior pillars cannot injure the great vessels if the knife be kept at all times anterior to such plane; (*f*) that the space is divided into two cavities by a septum formed by the styloglossus and stylopharyngeus muscles. This in most cases protects the great vessels from purulent infiltration. Failure of this septum to act explains the cases cited by Bosworth where pus passed along the great vessels into the mediastinum.

In conclusion, I wish to express my thanks to Professor Dwight, of the Harvard Medical School, for both advice and material, and to Dr. H. P. Mosher, for his excellent photographs and drawings, and for much valuable assistance in the preparation of specimens.

Clinical Department.

A CASE OF SEPTICEMIA TREATED WITH NORMAL SALT SOLUTION.[1]

BY CARROLL E. EDSON, A.M., M.D., DENVER, COLO.

DURING the past ten years increasing attention has been directed to the intravascular employment of normal salt solution in cases other than of hemorrhage. Since 1896 especially has its use been tried in cases of general sepsis of varying origin. The considerable and exceedingly interesting literature upon the subject was well summarized in an article by Dr. T. F. Reilly in the *Medical Record* of November 12, 1898.

I report the following case as a clinical contribution to the increasing number of successful cases that I may help, in whatever small measure, call attention to this ready and simple means of combating what has else been too often a prolonged and hopeless struggle.

I regret the absence of full bacteriological and blood examinations. I should not ask attention to an imperfect protocol were it not for the striking and suggestive lesson which the case affords.

C. M., age twenty-six, single, an electrical engineer, had been under my close observation for a year, during which time he had two typical attacks of follicular tonsillitis. The family and previous personal history have no bearing upon the illness under consideration. In 1896 and 1897 he had a severe and rather prolonged fever, which may have been typhoid, although reported not to have been. His habits and conduct of life had been exemplary and his health always good.

In the spring of 1898 he was much overworked, and from the first of May until his illness in November had in addition to overwork great business responsibility and anxiety. He was much run down and sleeping poorly. Early in November he suffered from a moderately severe attack of an infectious angina then epidemic in Denver. The throat was intensely sore and there was considerable glandular swelling in the neck. The tonsils were not more involved than the rest of the throat. There was no follicular exudation. No bacteriological examination was made, but the case was similar in every way to others during the epidemic in which cultures were made, and was probably due to a streptococcus infection. Recovery was slow, with great prostration. He returned to work too soon, against advice. During the next week at the office he complained of muscular soreness and weakness.

On November 24th his throat, which had been slightly uncomfortable, became very painful again and there was great backache, headache and high fever. During the next two days the attack ran a course similar to the first, save that there was more general pain tending to localize itself about the joints. On this account treatment by salicylates and alkalies was given, with anodynes and opiates. No relief was obtained. The muscular and joint pains became worse although there was little or no swelling. There was great difficulty in securing sleep; the temperature remained high, and it was evident that the illness would be prolonged.

On the 28th the condition became rapidly worse. While the temperature and pulse remained where they had been for several days, in the neighborhood of 101° and 110 beats per minute, the respirations rose to 35 and soon to 40. There was no conscious dyspnea, no local pleuritic pain to be distinguished from the great muscular aching everywhere present. Careful examination disclosed nothing more than a small area in the middle of the upper lobe of the right lung, with very slightly heightened percussion note and harsh and distantly exaggerated breathing. The heart was negative, and it may here be stated that daily examination never revealed any evidences of endo- or pericardial lesion.

For the next three days there was much intestinal distention, with a good deal of tenderness, which was not localized. There was some vomiting and troublesome belching. The bowels were finally opened by calomel, salines, and high enemata and the gaseous distention relieved by repeated enemata of asafetida mixture. During the rest of the illness there was fortunately no disturbance from the intestinal tract, and, with the exception of a few days during which there was slight febrile albuminuria, the urine remained normal.

The area of suspicious import in the lung did not increase and there was no development of any actual pneumonic process. There was lingering and rather shifting evidence of slight congestion over small patches in the upper right lung for a week or more. The respirations however remained continuously rapid

[1] Read before the Medical Society of the State of Colorado.

and rather shallow. The pains rapidly became absolutely crippling. The knees, ankles, hands, elbows and shoulders were successfully and irregularly invaded.

There was only very moderate swelling, which appeared to be not so much in the joints as an edema in the tissues about them. Over the backs of the hands this was especially noticed. There was at times a very faint blush over small areas, but never noticeable unless looked for. There was also very great tenderness over the muscles. Indeed, it was difficult at times to say whether the pain, which made it almost impossible to move or care for the patient, was caused so much by the motion of the joints as by the pressure upon the muscles. The best, though only slight, relief obtained was from painting the parts with 20 per cent. ichthyol and wrapping them in water with hot bottles outside.

There was almost absolute insomnia, and the few moments' rest obtained was marked by incessant delirious conduct of business affairs. For a while trional gave a little rest, but codeine, chloral, morphine, laudanum or even hydrobromate of hyoscine had little effect in quieting the increasing restlessness, and none procured any satisfactory sleep.

The condition on the 5th of December was most desperate. The temperature chart did not convey any idea of the illness, and is not reproduced for that reason. There was marked emaciation and a frightened look of distress upon the ashy face which can hardly be described. The decubitus was one of complete muscular relaxation, the limbs helpless from the pain, which made the patient moan if he saw any one even approach the bed. The temperature remained steadily between 101° and 102°, the fever being slightly higher on alternate days; the pulse, varying from 110 to 118, was weak, small and compressible, but regular. The respirations remained constantly rapid, about 35, but from time to time there were periods of great distress in breathing unexplained by any discoverable cause. There was very great restlessness, amounting to jactitation much of the time, insomnia and delirium at night, and by day a curious mental state of apparently clear cerebration which, however, was not real. Close watching showed that the mental processes were decidedly clouded and the patient has no recollection whatever of the events of some ten days. There were no rigors or marked fluctuations in temperature, but the man was frequently chilly. Considerable soothing followed hot alcohol baths. Despite nourishment, which was well taken, and abundant stimulation (sulphate of strychnine, one-thirtieth of a grain subcutaneously every four hours, and five drachms of whiskey every two hours), the patient was evidently fast succumbing to the septic invasion.

The injection of normal salt solution into the tissues seemed to offer slight hope and its use was approved by Dr. W. H. Bergtold and Dr. C. A. Powers, who saw the patient with me. At four o'clock on the afternoon of December 5th Dr. Powers injected sixteen ounces of hot sterilized salt solution into the subcutaneous tissues about the breast. Following the injection there was perhaps slight improvement in the restlessness and several quiet naps of from ten to forty minutes. There was an abundant and considerably increased flow of urine in the next twelve hours, nearly double the amount of the corresponding length of time before. Between 12 and 2 A. M. there was a period of very great restlessness and excitement, during which time it was very difficult to keep him in bed.

The morning of the 6th there was no especial improvement in the temperature, pulse or respiration, but the pain was decidedly less and the general condition seemed to warrant a continuation of the treatment. At 8 A. M. twenty-six ounces were injected slowly into the median cephalic vein. The injection caused great distress, a pulse of 120 and respirations of 40, with marked excitement for a short time, and profuse perspiration. Two hours later there was a sharp rigor lasting twenty minutes, the temperature rising from 100.6° to 103.8°. Following this the temperature fell gradually to 99.8° at 4 P. M., the lowest since the beginning of the illness. During the day the patient was much quieter than he had been and there was no note of any pain. The legs and arms were much less tender and the hands were used a little. At 8 P. M. the temperature rising to 100.8°, and there being a little return of pain, a third injection of eighteen ounces was made, this time under the pectoral muscles, as there seemed less disturbance and equally good results from intracellular injections. Following this there was no chill and only moderate sweating. A good deal of quiet sleep, with only light whispering delirium, was had during the night.

On the 7th there was much relief from pain in the morning, but during the day the restlessness, delirium and pain returned, and at 4 o'clock P. M. the temperature, pulse and respiration all being higher than for two days, a fourth injection of fourteen ounces was given. All the symptoms at once abated, the pain and the tenderness first. The pulse rate became lower and the quality better. The general expression of improvement was more marked than the signs of the chart.

On the 9th there was a rise of temperature which led to the consideration of further saline infusion, but this was postponed for signs of increasing pain, which did not develop. A similar rise on the 13th also proved a false alarm.

The subsequent history has nothing of general interest. The mild delirium lasted a long time, as did moderate fever and great weakness. The emaciation was extreme, and the patient absolutely unable to help himself simply from muscular weakness. Convalescence was necessarily slow after such an illness, but was uninterrupted, and by the first of June, 1899, complete.

The interesting features of this case were, *first*, the nature and location of the septic process. While I lack all bacteriological proof, I am inclined to think it was due to the streptococcus for the following reasons: It followed directly upon the recrudescence of an infective angina which was clinically the counterpart of others in which the streptococcus was found, and the absence of any suppurative process. A general typhoid infection was ruled out by the clinical picture of the illness, the absence of Widal's reaction and the probable typhoid character of the illness a year before. Nor was the picture one of a pneumococcus infection in the lungs. There was no consolidation, no characteristic expectoration. That the focus of infection starting from the throat became secondarily located in the lungs I am inclined to believe from the coincident appearance of the profound sepsis, the very rapid breathing and the signs pointing to moderate congestion. The shifting nature of these signs was

also a point in favor of a streptococcus invasion. There may have been some localization in the joints, but the pains seemed rather those of secondary irritation from absorbed toxins. This can of course be only conjecture.

Secondly, the very noticeable relief obtained by use of the salt solution. The lessening and cessation of pain, the quieting and clearing effect upon the brain, and the improvement in the pulse and whole general appearance were very striking. That this was not a chance coincidence seems proved by its immediately following four separate injections, the symptoms having returned after the lapse of a number of hours. Certainly up to the time of the first infusion the patient was steadily and rapidly failing; from that time began his recovery.

Lastly, the ease with which large amounts of salt solution can be injected under the skin if the fluid be allowed to run in slowly with gentle massage, and the quickness with which it is absorbed. So far as I could see, in this case the relief from the subcutaneous injections was quite as marked as from the intravenous infusion, while the disturbance seemed less. Other observers, however, have reported similar excitement from the subcutaneous use of the fluid. The sweating and free urination were noticeable after each injection.

Should I be so unfortunate as to see another so severe a case, I would make early use of repeated saline infusions, which can certainly in the light of our present knowledge do no harm, and which offer such encouraging results.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

(Concluded from No. 3, p. 64.)

RETRODISPLACEMENT OF THE PREGNANT UTERUS.

STORER[8] in discussing the subject says that there are no symptoms of consequence until about the tenth week, and they may be further delayed in a large pelvis. Spontaneous cure is limited by four things, adhesions, the sacral angle, the character of its displacement and its degree. The patient is often unaware of trouble until pressure symptoms come on. Urinary symptoms are apt to be the first thing noticed, more or less severe interference with micturition preceding actual retention. This is due to the upward pressure of the cervix on the urethra in versions of the uterus, and to a dragging on the urethra in flexions of the uterus. Constipation is also an early symptom. Upon examining a case of incarceration an exaggerated discoloration of the vulva is seen, and an extreme bulging of the perineum, which in one case, the result of a violent effort, caused a central rupture of the perineum and protrusion of the fundus. In flexions the cervix is accessible and not softened as usual in pregnancy, but there may be enormous hypertrophy. In uterine versions the cervix disappears behind the pubes often out of reach. The diagnosis is often very difficult. The displacements may become corrected as pregnancy advances, or pregnancy may go on to full term, the uterus becoming sacculated. Abortion more frequently occurs, although the retroflexed uterus has difficulty in expelling its contents and the fetus may be retained months after its death. If abortion does not occur grave results generally ensue without treatment, and 77 cases of death have been collected, mainly from sepsis, uremia and rupture of the bladder. Treatment is, first, to empty the bladder, which is often a difficult matter, and then attempts at replacement by manipulation are made. These consist mainly of depressing the cervix by traction from below and by pressure from above with fingers behind the pubes and at the same time pressing upwards on the fundus to release it, causing the uterus to revolve upon itself rather than attempting to force it up bodily. Elastic pressure in the form of water-bags in the rectum or vagina has been of service. If taxis fails, the patient's condition is good, and no urgent symptoms present, an expectant policy is advised up to the end of the fourth month, using careful packings, the knee-chest position, etc. Finally, an abdominal operation results in easy replacement without any great danger to the mother and with a better prognosis for the child.

OPERATIONS DURING PREGNANCY.

Noble[9] reports the results of his experience, which embraces twelve cases: one of myomectomy, one of hystero-myomectomy, one of appendicitis with abscess, one of intestinal obstruction after labor, and one of fistula in ano. The patient upon whom myomectomy was performed aborted, the operation having been undertaken for supposed ovarian tumors. He considers the operation not justifiable under ordinary circumstances during pregnancy. One other patient aborted, but the ovum was already dead before the operation, which only hastened the inevitable. All of the ovariotomies did well; in none of them was there the least difficulty in performing the operation, and in every way the patients made as good recovery as though they had not been pregnant. His experience corresponds with that of other surgeons and is in happy contrast to the results of the let-alone practice which so often leads to difficulties in delivery, and unless prompt and intelligent operative measures are taken, to the bruising, infection and necrosis of the tumors, with peritonitis subsequent to labor. In the case of intestinal obstruction, which proved fatal, the operation was complicated by the seven months pregnant uterus, which greatly increased the difficulties of finding the trouble in the abdomen and in dealing with the adherent bowel after it was found. This leads him to believe that it would be wiser in such a case, when dealing with so serious a condition as obstruction, to promptly do hysterectomy and get the big uterus out of the way, and then proceed in a systematic way to do whatever is necessary. He believes that all ovarian tumors which are recognized during pregnancy should be promptly removed even if quite late, as the risks of operation are much less than the risks of delay. Fibroid tumors should not be operated on during pregnancy unless for some very special reason. With reference to general operations in various parts of the body, while there is little danger of bringing on an abortion, yet he believes the indications for operations should be marked, that is, evidence should be present that the patient's life or health would be jeopardized by leaving the condition to continue until after labor.

[9] American Gynecological and Obstetrical Journal, April, 1899.

HYSTERECTOMY FOR PUERPERAL SEPSIS.

Goffe[7] says the question or even the propriety of hysterectomy for puerperal sepsis has yet to be determined, as there is no affection in which it is more difficult to lay down general principles of action. Two definite forms of puerperal sepsis are recognized, sapremia and septicemia. The former is the result of the absorption of toxins or ptomaines secreted by germs growing upon a putrefactive focus. These are the products of the less virulent forms of bacteria, and the progress of the disease depends largely upon the resisting powers of the patient. Such cases are characterized by a chill and a sharp rise of temperature early in their history and by offensive lochial discharge. They should be promptly curetted with antiseptic douches, free drainage of the lymph vessels kept up by catharsis, and the patients stimulated and nourished well. If the symptoms then are not arrested, but there are signs of constant infection, indicated by continual rise of temperature, tenderness over the uterus, chills and languor, the question of operative interference arises. If on the other hand the infection is that of the pure streptococcus, the curette has no place. It simply breaks down the resisting zone and opens the way for ready entrance of the bacteria and in the more serious cases it cannot do good at the time of recognition of the disease, as the invasion has already passed beyond its reach. The nature of the treatment must be such as to assist the resisting power of the uterus against the invasion of bacteria. Bumm, the German pathologist, found that under favorable conditions an inflammatory exudate is found around the seat of invasion, which, aided by the phagocytic action of the white corpuscles, prevents penetration of bacteria to adjacent tissues, and the process is thus limited to a circumscribed area. But in more severe infection, or with less resisting power of the tissues, the bacteria break down the protective zone, enter the lymphatics and veins, and toxins and micro-organisms are carried through the system. A case of puerperal sepsis at the Polyclinic is reported at length. Curettage was first performed and afterwards abdominal hysterectomy, uterus and broad ligaments removed *en masse*. The walls of the uterus were studded with collections of pus, also ovaries and tubes contained pus. The patient died of exhaustion following septic pneumonia on the thirty-sixth day after operation. The author questions whether the fatal result was due to the delay in the radical operation, and if not what measures, if any, might have been used to prevent the case reaching the condition where radical procedure was necessary.

THE EFFECT OF POSTURE IN DELIVERY.

Dickinson[8] at some length reviews the literature and the experimental work done on the effect of the Walcher, the Trendelenburg and the Mercurio postures in altering the size and shape of the pelvis. The literature of the subject is considerable and the opinions of the different authors greatly at variance, but his studies lead him to made the following deductions:

(1) Posture will notably alter the shape of the pelvis in late pregnancy.

(2) Increase in available room in the pelvic cavity as a whole cannot be brought about.

(3) To obtain the longest conjugate at the inlet, the hanging dorsal posture is to be employed. The gain is nearly one centimetre.

(4) To obtain the longest conjugate at the outlet, the full-flexed dorsal posture is necessary. The increase promises to be from one and five-tenths to two centimetres.

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN. MEETING AT COLUMBUS, O., JUNE 6, 7, 8 AND 9, 1899.

THE afternoon session was the first held by this Section.

DR. A. H. CORDIER, of Kansas City, Mo., thanked the Society for the honor conferred on him in choosing him its chairman, and in the Annual Address commented on the progress of gynecic surgery in the United States. There has been a resurrection of old methods, which have been made safe and life-saving. At the present time the adaptability of the human intellect, enabling it to accept the good and to reject the useless, is best evidenced in the medical profession. In commenting on the advances in the department of gynecology he spoke of the surgical treatment of cancer of the uterus, which has been so unsatisfactory in many respects; yet early surgical intervention is justifiable. Calcium carbide has proved no more useful for this terrible disease than many other remedies that have been advocated. In cancer early and correct diagnosis is most important. The early recognition of gonorrhea and the avoidance of uterine sounding diminish the number of cases of pelvic suppuration. A few years ago vaginal enucleation of the uterus and adnexa for pus practically caused a war in the profession. In operating for abnormal conditions both the vaginal and the abdominal methods have their good points, but he chose the abdominal route as being more complete and almost perfect. In the treatment of the insane the neurologist and gynecologist should work together. In operating on the insane relief of pain and better general health only should be promised, and the alleviation of mental condition hoped for. Ectopic gestation is more frequently recognized than formerly. All cases should be operated on as soon as recognized, unless gestation be near its normal termination, when it is a question whether to wait or not for the viability of the fetus. The abdominal route should be preferred in the treatment of extra-uterine gestation. Serious hemorrhage may occur by vaginal incision, which would necessitate celiotomy for its control. The loss of the child in cases of contracted pelves can now be avoided by the selection of obstetric operation. Post-partum douches are not only useless but harmful, and should only be employed in women with gonorrhea, for the protection of the child's eyes. The origin of puerperal sepsis, and its production by unclean hands and instruments, are more clearly understood. Serotherapy promises, in the near future, to be of much use, and, in his opinion, puerperal fever may be relieved by immunizing and curative doses of antistreptococcic serum. Credé's ointment of the soluble silver salts has produced very remarkable results in the hands of some observers, results that have been so sudden as to astonish the physician. Time alone

will determine the usefulness of this method in puerperal sepsis.

Dr. Augustus P. Clarke, of Cambridge, Mass., read a paper on

PELVIC TUBERCULOSIS,

in which he remarked that the sources of contamination of the serous tissue are numerous. The principal avenues of entrance are along the loins from the intestinal tract. The morbid conditions resulting in adhesions of a portion of the intestine to the Fallopian tube and the subsequent ulceration or perforation of the united surfaces furnish, no doubt, one of the means by which the bacilli reach the adnexa. From the intestine to the mesentery, and from that point to the peritoneum and to the uterine appendages the bacilli may pass uninterruptedly. In many cases, if not in most, tuberculosis of the genital tract occurs in connection with the general dissemination of the disease in the other organs. This not infrequently takes place in childhood and before puberty. Tuberculous lesions of the adnexa originating through the blood supply, though occasionally observed, cannot be regarded as a common process. The three forms of the Fallopian tubes usually mentioned may very properly be reduced to two classes, the miliary and the fibroid varieties. Miliary pelvic tuberculosis may not pass beyond the first stage, or the disease may remain latent for varying indefinite periods. It is in such cases that a mere abdominal incision may be followed by apparent recovery, but it is not safe to regard the seeming recovery that follows celiotomy resorted to for tubercular peritonitis as being permanent in results. The chronic form of fibroid tuberculosis, in which the connective tissue is greatly increased, may become arrested in its course or in recovery. The connective tissue in its embryonic development having, of course, its origin in the same fibrous layer tends generally to the production of conservative processes. The preternatural development of the fibrous tissue in the tube, ovary, or other pelvic structure exposes the mass to the danger of becoming, through its diminished vitality, the focus of malignant degeneration. Observation proves that the presence of bacilli in the testes of husbands of women who are found suffering from tuberculosis of the Fallopian tubes should not be regarded as being positive evidence that the disease has been the result of transmission of bacilli from the husbands, for such infection of the male genital organs may have first been imparted from the female.

Dr. H. A. Kelly, of Baltimore, feels sure that coitus has nothing to do with tuberculous infection, and has never seen a case due to that cause. The tubes are not frequently the site of the disease, although the uterus is affected more frequently than is generally supposed. In three cases he has made diagnosis by microscopic examination of scrapings from the uterine surfaces. Tuberculosis of the cervix is very rare, and he has seen one instance only. In operating, all diseased tissues should be removed. The tuberculous uterus should be extirpated. Retroperitoneal glands should be carefully examined.

Dr. E. E. Montgomery, of Philadelphia, reported a case of tuberculous disease of tubes and ovaries occurring in a girl thirteen years of age, the condition being associated with diverticulum of the bladder. The patient had suffered from inability to retain urine. The tuberculous appendages were removed. The bladder was irrigated later, and a decided improvement was noticed.

Dr. Goldspohn, of Chicago, believed that the removal of caseous tubes renders the development of tuberculous lesions elsewhere less probable. He believes that the uterus and part of the ovary, if possible, should be permitted to remain.

Dr. C. G. Frederick, of Buffalo, N. Y., reported a case of double tuberculous disease of the appendages in which he performed supravaginal hysterectomy. The patient had a tuberculous abscess developing later, which was opened by the vagina, and general pulmonary tuberculosis developed later. Ruth reported a case of large ovarian tumor, complicated with tuberculous omentum in which pulmonary tuberculosis developed.

Dr. Cumston, of Boston, spoke of pulmonary tuberculosis coexistent with tuberculosis of the vermiform appendix, and gave evidence that the infection did not have to come through the vagina. He does not remove the tubes unless they are absolutely degenerated, but opens the abdomen and thoroughly irrigates, and, as a rule, permits the tubes to remain.

Dr. James F. W. Ross, of Toronto, discussed the difficulty of diagnosis in these cases of miliary tuberculosis. Hemorrhage is often a symptom of tuberculosis of the appendages. It occurs most frequently in young, unmarried women and cannot come from infection through the vaginal tract. Marvellous cures result from simple celiotomy and irrigation.

Dr. J. R. Eastman, of Indianapolis, Ind., called attention to the importance of diagnostic curettage and microscopic examination, with isolation of the tubercular bacilli.

Dr. D. Tod Gillian, of Columbus, reported an interesting case of calcareous degeneration in a tuberculous condition in which the calcareous plates were removed and symptoms relieved.

Dr. C. A. Reed, of Cincinnati, reported a case of general miliary tuberculosis of the intestines. One year later pulmonary tuberculosis developed.

Dr. Dorsett advocated the injection of antiphthisic serum and reported a case in which it had been used successfully.

GYNECOLOGIC CONSIDERATIONS OF THE SEXUAL ACT.

Dr. Denslow Lewis, of Chicago, Ill., read this paper. He emphasized the fact that man first seeks to live, then he seeks to make others live. Medical men in their deliberations should take cognizance of this great factor in human life. Lewis believes that sexual matters should be taught the young at an early age. Girls particularly should know the usual consequence of sexual intercourse. Their modesty may be shocked but their virtue will be saved.

Papers by Dr. John S. Pearson, of Louisiana, Mo., on "Mothers of Yesterday, To-day and To-morrow," "Women of the Past, the Present and the Future," and by Dr. Edwin S. Ricketts, of Cincinnati, Ohio, on "Obstruction of the Biliary Ducts in Women," were read by title.

Dr. Clinton Cushing, of Washington, D. C., read the next paper on the programme, which was entitled

CHOLECYSTECTOMY.

Dr. Cushing assumes that the gall-bladder is not necessary to the health or well-being of the individual;

that it performs no physiologic function. The indications for surgical operations on the gall-bladder are: (1) Recurring attacks of biliary colic, with or without jaundice, whether the gall-bladder is enlarged or not; (2) enlargement of the gall-bladder whether there be pain or not; (3) persistent jaundice, which is preceded or accompanied by pain in the region of the gall-bladder with or without paroxysms resembling ague; (4) empyema of the gall-bladder or peritonitis in the region of the gall-bladder: (5) abscesses in region of gall-bladder; (6) when the gall-bladder is seriously diseased, as it is better than having it as a place for further accumulation of gall-stones or as a point of new inflammations.

THE ANATOMY OF THE ROUND LIGAMENT.

DR. J. WESLEY BOVÉE, of Washington, D. C., read this paper by title.

SECOND DAY.

WHAT SHALL WE DO WITH THE UTERINE FIBROID?

DR. D. TOD GILLIAM, of Columbus, read this paper by title.

DR. HENRY P. INGRAHAM, of Buffalo, read a paper entitled

SPONTANEOUS RUPTURE OF THE BODY OF THE UTERUS DURING LABOR.

In investigating 48,000 cases of labor, 12 cases of ruptured uteruses had occurred, five of these being traumatic and seven spontaneous. Most of the cases occured in the practice of midwives. A large proportion of the cases occur among the foreign-born population. Many cases are unrecognized. The condition, however, is less frequent now than formerly, owing to the advances made in obstetric technic.

In the discussion which followed the paper, DR. GOFFE, of New York, said he thought many cases of uterine rupture were unreported. He reported a case in which death occurred without marked symptoms, in which the autopsy revealed complete rupture of the uterus, and also a unique case in which the uterus had been torn away by the vagina, it having been mistaken for the placenta and removed with the child.

DR. BALDWIN added four cases to the list of ruptured uteruses; in three of them death occurred.

DR. FITZGIBBON, of Milwaukee, in a paper entitled

UTERINE FIBROIDS,

discussed the varieties and position of these new growths. The purely myomatous tumor is rarely found. Various degenerative changes were described. The direct causation of these tumors is unknown. The colored race are very frequently affected. The symptoms were divided into (1) constitutional; (2) uterine; and (3) those due to pressure. Early diagnosis is sometimes difficult. Fibroids may be diagnosed as pregnancy, retained menses, flexions, malignant disease, subinvolution and inflammatory exudate, and these in turn may be mistaken for fibroid. Treatment may be non-surgical and surgical. Ergot is the best styptic, although hydrastis is often valuable, but the intra-uterine use of styptics is to be condemned. Electrolysis is not satisfactory. Surgical treatment is palliative, either the vaginal or abdominal route being used according to indications. Ligation of the uterine arteries and broad ligament is not advisable. Oöphorectomy has its uses in some cases. The intraperitoneal method of hemostasis is preferable. Myomectomy may be used in subserous fibroids. In section the abdominal incision should be made high to avoid injury of the bladder. Injury to the ureter is the greatest danger to be avoided. Three complicated cases were described in detail.

In discussion, DR. G. BETTON MASSEY, of Philadelphia, condemned the use of the term "electrolysis," meaning a chemical dissolution of the growth. He prefers the phrase "electricity applied by a careful technic." If results are not secured in a year let the case be turned over to the surgeon. The use of oxychloride of mercury at the seat of application is advocated. In hemorrhagic cases and small tumors he advocated the use of electric treatment.

DR. WM. H. WATHEN, of Louisville, Ky., condemns the extraperitoneal method of treating the stump in hysterectomy for fibroids, believing it to be unsurgical and unscientific. If the cervix is permitted to remain there is a possibility of degenerative changes in it. He believes electricity has no field in these cases and that it does untold harm. We should be conservative, but when the ordinary medical treatment fails, surgery should be employed. Myomectomy is the ideal method in these cases.

DR. T. A. REAMY, of Cincinnati, O., thinks that electricity has its uses. He has knowledge of 50 cases in which the symptoms have been relieved, and protests against a dogmatic condemnation of methods other than surgical.

DR. H. D. MARCY, of Boston, is thoroughly satisfied that electricity produces no material benefit. He had invited Apostoli to demonstrate his method in his hospital, and watched the results, which were unsatisfactory. The consensus of opinion in two continents is in favor of the surgical rather than the electrical method.

DR. ALBERT GOLDSPHON, of Chicago, believes that electricity relieves the pelvic hyperemia, and that this result can be obtained without the use of an electrode in the uterine cavity, or an invasion of the endometrium. The extra-uterine method of electrical application is the best. In hysterectomy he prefers complete removal of the uterus.

DR. JOSEPH R. EASTMAN, of Indianapolis, believes that the delay occasioned by using electricity is detrimental to the patient and that the surgeon is best qualified to decide which cases should be treated surgically and which electrically. The use of electricity is exceedingly limited. The selection of method is to be suited to the individual case.

DR. PALMER thinks that the treatment must be adapted to the individual case. A study of the history of the case must be made. The use of medicines is very unsatisfactory, but ergot and hydrastis are the two most useful drugs we possess for the condition. He considers Baer's operation the best to employ when operation is advisable. Curettement does good in many cases. He believes it will arrest the growth and diminish the size of the growths.

DR. J. WESLEY BOVÉE, of Washington, advised the application of any method that will relieve the individual case, and also directed attention to the danger of curettage in these cases, sepsis occurring afterwards.

DR. JOHN B. DEAVER, of Philadelphia, in his paper on

said that the frequency with which postpuerperal sepsis occurs even at the present time, with our knowledge of asepsis in surgery, calls for discussion. He reported a case of tubo-ovarian abscess with infection of the uterus following childbirth, in which the uterus, right tube and ovary, and left tube were removed. There are three forms of puerperal sepsis, from an anatomic standpoint, all of which are infectious and due to abrasion of the mucous membrane lining the cervical canal and uterus. They are endometritial, metritial and parametritial. The most fatal form is the metritial form. It is characterized by multiple fossa infection and abscesses. The endometritial is the most amenable to treatment, namely, curettement of retained decidua and thorough disinfection of uterine canal. The parametritial form is most frequently mistaken for so-called pelvic cellulitis. Puerperal sepsis is of two varieties: that due to putrefactive changes in the retained portions of the decidua or blood clots, and that which is the result of the introduction of micro-organisms by means of denuded endometrium, through the sinuses, or as the result of injury to the external genitals following the use of instruments during labor. Dr. Deaver believes that the conditions frequently described as cellulitis and abscess originated from sepsis carried into the tube and through the tube into the pelvis, where the inflammatory exudate breaks down and forms an abscess which is circumscribed by an adventitious membrane so closely resembling peritoneum that operators pronounce it as such, and regard the case as one of abscess of broad ligament. He believes the curette is resorted to too often. It is an instrument that requires as delicate manipulative skill to use with safety as the lithotrite, and should be handled with the greatest care and gentleness. Two cases were reported in which the uterus had been perforated with the curette. In one case examination revealed the presence of a loop of intestine in the vagina. Celiotomy was performed and six inches of small bowel was found, semi-gangrenous, and devoid of mesentery. The perforation in the uterus was about the size of a five-cent piece. Supravaginal amputation of the uterus with removal of the tubes was performed, the involved portion of the ileum resected, and end-to-end suture with needle and thread performed, the abdominal cavity thoroughly irrigated and drained, but death occurred from peritonitis on the evening of the fourth day. The treatment of septic endometritis was dealt with. Dr. Deaver prefers mercuric chloride and carbolic acid to lysol as an antiseptic. Several cases of pelvic abscess were described which illustrated the valuable point that the early institution of so-called radical measures is true conservatism in surgery.

In the discussion which followed the reading of Dr. Deaver's paper, Dr. Charles P. Noble, of Philadelphia, said that he believes that usually injuries to the uterus can be quickly and safely repaired, and prefers doing so to hysterectomy in cases of perforation.

Dr. B. Sherwood Dunn, of Boston, Mass., emphasizes the use and abuse of the uterine curette. He has seen two total hysterectomies as a direct result of the use of the curette. Curettement is a delicate operation and should be done with scrupulous and rigid aseptic precautions.

Dr. Henry T. Byford, of Chicago, Ill., advocates the use of the finger to guard the curette, or to remove retained secundines from the uterine cavity. Thorough curettage is necessary to remove adherent shreds.

Dr. Dorsett thinks that not one general practitioner in fifty should be allowed to use a curette. It requires as much skill as the most delicate operation in surgery. He advocates thorough cleansing and drying of the uterus and the insertion of a suppository of from 20 to 40 grains of iodoform, and the use of a gauze drain protruding into the vagina in cases of sepsis.

Dr. Henry thinks none but a bungling operator would perforate the uterus with a curette. He uses pure carbolic acid to swab out the uterus and no drainage.

Dr. Haggard believes that although the curette may be sterile, yet the endometrium is not, and a sharp curette disturbs the barrier nature has provided. The finger and the Bozeman dressing forceps for cleansing the uterus, and drainage, with irrigation with a 40-per-cent. solution of alcohol at frequent intervals, are useful. He does not believe that iodoform gauze drains effectually.

Dr. Paddock believes that physicians who do not know how to use the curette should not practise obstetrics. Irrigation should be practised prior to curettement. The finger is not long enough to reach the entire uterine surface. The dull and not the sharp curette should be used.

Dr. T. A. Reamy, of Cincinnati, uses a lithotomy forceps deprived of its teeth, for exploration.

Dr. Chauncey D. Palmer, of Cincinnati, believes the finger is totally unadapted for emptying the uterus at term. He uses the dull curette after all abortions or after parturition at term.

Dr. Duff believes the same result is obtained by all methods, and discussed the etiology of puerperal sepsis. Many cases are caused by placenta succenturiata and placenta spuria. Many cases are overlooked and all placentas should be carefully examined and the uterus explored for retained fragments.

At the afternoon session a symposium on

VAGINAL VERSUS ABDOMINAL SECTION

was held. A paper entitled

VAGINAL OR ABDOMINAL SECTION IN PELVIC SURGERY,

by Dr. M. V. Ball, of Philadelphia, was read by title.

THE ADVANTAGES OF VAGINAL SECTION IN THE SURGICAL TREATMENT OF PELVIC DISEASE IN WOMEN.

Dr. J. Riddle Goffe, of New York, read this paper. He believes that thorough and complete work can be done by the vagina. Celiotomy is a serious thing. The objections are (1) stitches; (2) adhesive plasters, which are annoying; (3) binder; (4) abdominal scar; (5) danger of ventral hernia. Great diversity of opinion exists in regard to the closure of abdominal incision. By vaginal incision is implied not simply puncture, but a free incision, transversely, if necessary, and supplemented by incision posterior to the cervix, giving ample room for manipulation. Vaginal fixation has many objections. Goffe prefers the vaginal shortening of the round

ligaments. He considers this the ideal treatment for retrodisplacements. No disadvantages during pregnancy occur and it is superior to suspensio uteri and the Alexander operation. The objections to the Alexander operation are many, because (1) of its limited applications; (2) ligaments are often absent or weak; (3) two unsightly scars are caused; (4) there is danger of hernia, which has frequently occurred subsequently. Retroversion is best treated by shortening of round ligaments through the vaginal incision. Diseased appendages may be removed, adhesions may be broken up, and malpositions corrected. Pelvic abscesses can be treated thoroughly, satisfactorily, and safely by vaginal incision. If both adnexa are destroyed total hysterectomy is indicated. The intestines may be injured, but this accident also occurs during abdominal operations, but less frequently in vaginal than in abdominal section. Ectopic gestation, ovarian dermoids, fibroid tumors of the uterus, may all be dealt with by the vagina. The pain is much less and the convalescence smoother than after celiotomy. The simplicity and facility and comfort of this method commend it to every operator.

TECHNIC OF SURGERY OF THE UTERUS AND ADNEXA PER VAGINAM.

DR. WILLIAM H. WATHEN, of Louisville, Ky., who read this paper, said he believes that many cases may be treated equally well either by vaginal or abdominal section. The bisection of the uterus increases the value of vaginal section. After the uterus is bisected, each half may be brought outside the vulva. He has never wounded ureter or intestine by the vaginal incision, but has been less fortunate in operating by the abdominal method. The adhesions above often prevent the prolapse of the intestine into the vaginal incision. There is less danger of infecting the peritoneum, or of post-operative sequels than in celiotomy. Too many instruments are generally employed in doing vaginal hysterectomy, which prevents perfect surgery. One retractor is sufficient. In early tubal pregnancy the ruptured tube may be removed by the vagina, unless the peritoneal cavity is filled with blood. Wathen has operated on 35 cases of ectopic pregnancy by this method without an untoward symptom. Post-operative septicemia may be treated and its further invasion prevented by vaginal incision and drainage.

A paper by DR. JOSEPH PRICE, of Philadelphia,

WHAT BECOMES OF THE PATIENTS AFTER VAGINAL CURETTAGE AND DRAINAGE?

was read by title, and DR. FERNAND HENROTIN, of Chicago, contributed a paper with the same caption. He advocated vaginal incision. The conditions for which it is now performed were detailed. It is adapted to women with capacious vaginas and thick, adipose abdominal walls, or in case of cardiac weakness. The post-operative symptoms are so slight that many patients cannot believe any serious operation has been performed. The objection has been offered that these operations are incomplete, yet he believes that the operation by the vagina is ideal and truly conservative of function. Pus may be either intraperitoneal or extraperitoneal, and most frequently secondary to pyosalpinx. Diseased tubes may be better removed through the suprapubic incision, although pus may be evacuated through the vagina and cure follow. Ovarian abscesses may be treated by the vagina without removal of the ovary. Results depend upon the discrimination and skill of the surgeon. About 25 per cent. to 30 per cent. of cases of pelvic disease may be advantageously operated on by the vagina.

In the discussion, DR. H. A. KELLY, of Baltimore, said he agreed with Dr. Henrotin's views on the subject of vaginal section. Opinions have been radically changed during the past few years. Segond had long before advocated these methods, which, at that time, we consider was operating in the dark. Dr. Kelly is an adherent of both methods, preferring the abdominal method in diseased conditions affecting the upper part of genital tract, that is, conservative operation on upper portion, and using the vaginal route for disease below. For pelvic abscess the vaginal route is the method *par excellence*, that is, in abscesses of ovaries and tubes, which are usually of gonorrheal origin. He gave statistics of 59 cases in patients from whom he had received letters, detailing the conditions a long time after operation. Of these, 39 were practically improved, showing very slight symptoms. Nine were still suffering some symptom. Four died, three from uremia, and from general infection. Some of these cases were operated on while in a critical condition. Many spoke of having only begun to improve six months or a year after operation, and several of the patients now well suffered greatly for the first months. Rectovaginal fistula occurred four times, the sac having ruptured into the rectum, and when puncture was done between rectum and vagina, became complete. Of these the fistula was healed in three cases and unhealed in one.

DR. JOSEPH R. EASTMAN, of Indianapolis, is an advocate of the vaginal method in selected cases. In fibroid tumors the operation will depend on position of growth, whether it is pedunculated or not and the character of pedicle. He prefers the Sims position in working by the vaginal route, as he considers certain advantages are gained thereby. Small ovarian cysts may be removed after tapping by this route. Both routes have advantages, and selection will depend on the individual operator.

DR. J. B. MURPHY, of Chicago, believes that the patient should be cured by one operation, if possible; that after incision of a gonorrheal pyosalpinx through the vagina, and after the incision has been healed, subsequent stricture of tube will interfere with drainage of the tube, and the patient will suffer from much discomfort later. In case of postpuerperal infection abscesses that form may be cured by vaginal infection. The pathology and origin of abscess must be considered. He should advocate the abdominal route for infection in cavities lined by epithelial cells, and the vaginal route for abscesses in the connective tissue.

DR. E. P. DAVIS, of Philadelphia, considers that the vaginal route is particularly useful when an abscess has formed. The uterus should be saved, if possible. He believes that the abdominal route is preferable in cases of gonorrheal infection.

DR. CHARLES P. NOBLE, of Philadelphia, thinks that vaginal puncture is an unfortunate term. A large incision should be employed and is indicated. Very seriously ill persons may be saved that certainly would die if celiotomy was performed. In many cases pregnancy will occur subsequently. In the majority of cases he employs the abdominal method. He believes

that the objection to the abdominal scar is very rare, as the style of women's dress has not changed so that it is necessary for this scar to be exhibited. Concealed hemorrhage may necessitate celiotomy to save patients after the vaginal incision. Many accidents to uterus, appendages or bladder may occur during the procedure.

Dr. C. A. L. Reed, of Cincinnati, said the value of such discussion is that it brings out the truth that these operations, formerly opposed, are but supplemental. A few years ago the edict came from England that all such conditions should be treated by the abdominal route. Then came from France, almost immediately, the word to attack all such by the vagina. We have since been able to recognize that perhaps there is a soul of truth in all things false, as well as a soul of good in all things evil. When to adopt one method and when the other is only to be determined clinically and upon the spot, and frequently after the initial steps in the operation have been taken. To presume to determine beforehand just what condition will be found and what procedure will be adopted presupposes a degree of diagnostic acumen which he does not claim to possess.

The following papers were read by title:

"Pelvic Inflammation," by Dr. O. Beverly Campbell, of St. Joseph, Mo.

"Lymphatics of the Peritoneum," by Dr. Byron Robinson, of Chicago, Ill.

"Surgical Significance of Certain Physiologic, Anatomic, and Pathologic Peculiarities of the Peritoneum," by Dr. H. D. Niles, of Salt Lake City, Utah.

Dr. Augustin H. Goelet, of New York, presented a paper on

TREATMENT OF ENDOMETRITIS BY DRAINAGE AND IRRIGATION,

in which he declared it was an error to regard every uterine discharge as evidence of endometritis and to treat such conditions by caustic and astringent applications which coagulate the discharge and defeat drainage by blocking the orifices of the glands. This and destructive curettage he designated unscientific. Hyperemia with hypersecretion, often mistaken for endometritis, reqires no local application to the endometrium, in fact is often converted into an endometritis by such treatment. The danger of inserting instruments into the uterus, either for the purpose of diagnosis, treatment, or for operations, when there is a so-called catarrhal endocervicitis, was pointed out. He declared that the staphylococci, streptococci and gonococci are often found in the cervical secretion when it is most inoffensive in appearance, and that their presence or absence can only be determined by microscopic examination of the discharge. He insists that this method of examination should always be employed in these cases before the cavity above the internal os is invaded, either for the purpose of diagnosis, treatment or operations within the uterus. In endometritis the disease is not confined to the surface, but has invaded the glandular structure beneath, and he believes the rational treatment is to free the orifices of the glands and drain them until the infective process is exhausted, at the same time employing repeated irrigation with some non-astringent, non-irritating solution to remove the expelled secretion from the surface and prevent migration of infective germs. This may be accomplished by a carefully executed curettage done in a manner not to destroy the mucosa, but merely for the purpose of removing projecting granulations upon the surface or superfluous tissue that may be blocking the orifices of the glands and preventing drainage. The dull curette with rigid shaft, he thinks, is sufficient, and the sharp curette should not be used upon the endometrium of the cavity in endometritis. It is both unnecessary and unwise to attempt to remove the entire mucous membrane, and caustic applications should not be used after curettage in these cases. They cause necrosis, and atrophy of the mucous membrane or agglutination of the sides of the cavity may result. He urges that curettage should only be regarded a preliminary step in the treatment and that more attention be given to the after-treatment, which he deems most important; this to consist of persistent drainage and irrigation until all evidence of disease, as revealed by microscopic examination of the secretion and inspection of the cavity by means of the uterine endoscope, has been effaced. He also urges endoscopic examination of the cavity, both before and after curettage; before, to decide the actual necessity therefor, and after, to determine the completeness or incompleteness of the work. In this way only may errors be avoided. He exhibited a uterine endoscope with a small electric lamp placed at the extremity of the tube for direct illumination of the interior of the uterus, after the plan of the Valentine urethroscope. A megaloscope is attached for bringing out more prominently the details of the surface.

Dr. W. Branham, of Baltimore, in a paper on

PAPILLOMA OF THE OVARIES, OMENTUM, AND UTERUS; OPERATION; RECOVERY,

reported a case in which the uterus, ovary and part of broad ligament were removed. Vaginal drainage was employed and recovery ensued. No recurrence had been noted. An interesting point was the presence of elevation of temperature as a symptom.

Dr. W. H. Humiston, of Cleveland, Ohio, read a paper on

CLINIC AND MICROSCOPIC DIFFERENTIATION OF SCLEROCYSTIC AND CIRRHOTIC DEGENERATION OF THE OVARIES AND CHRONIC OVARITIS.

He thinks the etiologic factor in these cases is unknown. The cirrhotic ovary is smaller than the normal, is hard and inelastic and deeply corrugated. The sclerocystic ovary is two or three times larger than normal and is globular rather than ovoid. The pathology, symptoms, diagnosis and treatment were discussed. Internal medication is very unsatisfactory, and Humiston knows of no way to relieve this class of patients except by castration. Much may be done for chronic ovaritis by general supervision and by gynecologic treatment. Pelvic massage and galvanism, with tampons soaked in ichthyol and glycerin carefully applied to exert a slight pressure, will in a few cases greatly increase the mobility of the adherent uterus and its adnexa and relieve to a great extent the dysmenorrhea and ovarian pain. Usually symptoms gradually decline after the menopause.

THIRD DAY.

Dr. H. D. Niles, of Salt Lake City, read a paper entitled

SURGICAL SIGNIFICANCE OF CERTAIN PHYSIOLOGIC, ANATOMIC AND PATHOLOGIC PECULIARITIES OF THE PERITONEUM.

He believes that free movement of the pelvic and abdominal viscera is absolutely essential to the healthful performance of their normal functions; that the very existence of pelvic and abdominal surgery, with all its possibilities for the saving of life and suffering, depends not upon ordinary surgical knowledge and skill, but upon the extraordinary inherent power of the peritoneum to repair injuries, oppose disease, and overcome infection. The methods by which the peritoneum exercises its protective functions are (*a*) exudative or reparative, (*b*) absorptive or eliminative, and (*c*) phagocytic. The local and general conditions that influence the protective and eliminative powers of the peritoneum warrant the following conclusions: (1) Lessened blood pressure encourages absorption and consequently favors phagocytosis; (2) a normal heart and healthy excretory organs capable of excessive functional activity are favorable factors in the elimination of the pathogenic germs; (3) the smaller the quantity the less the virulence, and the more general the distribution of the pathogenic bacteria the more likely the peritoneum is to dispose of them; (4) any *locus minoris resistentiæ* may retard or prevent absorption and encourage exudation and the formation of adhesions; (5) foreign bodies always act as irritants and produce adhesions; (6) all peritoneal adhesions retard absorption, first, by providing a convenient place for concealment of pyogenic bacteria, and secondly, by interfering with the normal mobility and functional activity of the peritoneum. Any interference with normal peristalsis is detrimental; (6) phagocytosis is vastly more effective when a large area of peritoneal surface is brought into contact with a diluted infection than when a limited area is compelled to oppose a more concentrated infection. Finally, the foregoing conclusions support the belief that pathogenic germs, regardless of their number or virulence, may always be safely disposed of, provided that the surgeon does his work promptly and completely and is able to secure conditions that are favorable for these natural agencies to exercise their full protective powers. Dr. Niles believes that peritonitis is always a surgical disease; that early operation should at all times be the one of choice; that complete surgery always promises more than incomplete surgery; that preparatory and after-treatment should include active and effective measures for the reduction of blood pressure and increase of the activity of the phagocytic, absorptive and eliminative functions, and that a small incision, with the least possible exposure in handling, complete removal of *débris*, avoidance of animal ligaments and sutures, perfect repair of the peritoneum, thorough flushing and no drainage, are all important factors in securing the co-operation of these natural agencies.

In discussion, DR. DORSETT said he thinks flushing of the abdomen often distributes sources of infection throughout the peritoneal cavity, and is to be avoided.

DR. HUMISTON thinks the chances of recovery are very much better after the completed operation. Gauze packing may be so placed that infection of general peritoneum may be prevented. He uses drainage very rarely.

DR. B. MERRILL RICKETTS finds that adhesions occur even after complete and ideal operations. They are frequently present without symptoms being produced. He advocates as short an incision as possible in celiotomy.

DR. HENRY irrigates the abdominal cavity very thoroughly after operations for purulent collections in the pelvis. Several gallons of sterile saline solution must be used. To be effective large quantities of fluid must be employed. As a rule drainage is not necessary, and many cases that were formerly drained we find do perfectly well without it.

DR. FREDERICK HOLME WIGGIN uses hydrogen peroxide and later saline solution for cleansing localized pus cavities. All raw surfaces should be covered and every effort taken to prevent adhesions. If a large quantity of the saline solution is left in the cavity, it mechanically prevents the agglutination of the intestines and lessens the danger of subsequent adhesions or intestinal obstructions.

DR. RUFUS B. HALL, of Cincinnati, in a paper entitled

MANAGEMENT OF PREGNANCY COMPLICATED WITH ABDOMINAL TUMORS,

discussed ovarian and uterine tumors during pregnancy. These cases occur frequently enough to excite the interest of the profession in this subject. In properly selected cases operation for these conditions is indicated during pregnancy. The danger of abortion following operation has been very much exaggerated. No definite rule can be formulated to determine which cases will or will not abort. Pregnancy favors the rapid growth of all uterine and most ovarian tumors. The pregnant woman is not in an ideal condition for operation. The responsibility of advising the patient is great. A case of pregnancy at four and a half months, complicated with an ovarian cyst and general peritonitis, was described. Operation was done, but patient died in a few days. Other illustrative cases were cited. When abortion occurs the danger to the patient is greatly increased. Women with fibroids rarely become pregnant, and the decision in regard to operation will depend entirely on the individual case. If possible, the patient should be tided over until the termination of pregnancy. The position of the tumor in uterine wall will determine the management of the case, as operation will almost always require sacrifice of the uterus and fetus.

In discussion, DR. ROSENWASSER advocated operations for ovarian tumors during pregnancy, but in fibroids the question is more difficult to decide. Sepsis and hemorrhage are apt to occur after labor in these instances. Many die of septicemia.

DR. HUMISTON, in small tumors without symptoms, waits for delivery. In myomas, particularly those involving the lower uterine segment, the only safe procedure is immediate operation as soon as recognized.

DR. RICKETTS related an instance of severe postpartum hemorrhage in a case of labor complicated with fibroid.

DR. MASSEY thinks that if a powerful faradic battery were at hand at the time of delivery, the danger of post-partum hemorrhage would be effectually and certainly obviated. He asserts that one second would be sufficient to stop the hemorrhage.

DR. CARSTENS thinks that pregnant women bear operation well. A patient who is conscious of the presence of a tumor, complicating pregnancy, is very

much depressed by its presence, and this is an additional argument for operation.

DR. DORSETT described a case in which the patient was successfully delivered in the knee-chest position. He thinks that the danger of rupture of the uterus would be very much increased by the use of the faradic current to control hemorrhage.

DR. C. P. NOBLE, of Philadelphia, thinks the good results are due to the fact that these patients are not septic. He advises operation in all cases of ovarian tumors complicating pregnancy, and related a case in which one patient had had two ovarian tumors removed in two pregnancies. Dermoid or adherent cysts, particularly, should be removed, as gangrenous cysts are very serious complications. In regard to fibroid growths, his attitude is more conservative, and the conditions must be exceptional and extreme if surgical interference is employed.

DR. HAGGARD related an interesting case of large adherent ovarian cyst successfully removed during pregnancy.

The following papers were read by title:

"Indications for Treatment in Tubal Rupture and Tubal Abortion Consequent upon Ectopic Gestation in the Tubes," by DR. GEORGE TUCKER HARRISON, of New York.

"Treatment of Ectopic Pregnancy at or near Full Term, the Child Living," by DR. L. H. DUNNING, of Indianapolis.

"Data Concerning Deformities in Fetuses of Extra-uterine Gestation," by DR. ANDREW F. CURRIER, of New York.

(*To be continued.*)

Recent Literature.

A Century of Vaccination and What It Teaches. By W. SCOTT TEBB, M.A., M.D. Second edition. London: Swan, Sonnenschein & Co. 1899.

The author of this book is one of the foremost exponents of the antivaccinationist party in England, a section of the population which, unfortunately, has increased in Great Britain.

The book is a sample of the illogical methods which have been put forth by the antivaccinationists from the times of Jenner down to the present day, since the great and convincing facts relating to vaccination are here persistently omitted, while the unimportant matters are highly magnified.

The following is an example from the introduction: "Right through the century there has existed a body of officials ostensibly paid to promote the practice of vaccination, but also, partly at least, paid to vindicate it theoretically, and to explain away its failures and its accompanying disasters. But for this State aid, vaccination would long ago have been consigned to the same limbo as has received a thousand other similar fads, which, fortunately for the public, have not secured official recognition and support."

This statement is sufficiently disproved by the example of the United States, where, until quite recently, vaccination has been practised almost exclusively by private physicians without State aid, and because of their unqualified confidence in the efficiency of their practice. They were only following in the footsteps of two great exemplars, the first American recipients of vaccine lymph from England, — Waterhouse in the North and President Jefferson in the South. The supposition that either of these men were acting from mercenary motives is preposterous.

The author's argument as to the possible conveyance of syphilis by vaccination is almost entirely drawn from an early period, before the introduction of bovine lymph, and hence has little weight at the present day.

His quotation in regard to the Montreal epidemic of small-pox in 1885 is incomplete, in that the fact that the mortality fell most heavily upon the unvaccinated French-Canadian population is kept out of sight.

Again the following statement in regard to vaccination in Germany (p. 235) is misleading. "It will thus be seen that, since the year 1834, there have been 7,505 cases and 291 deaths from small-pox in the German Army."

Now, the compulsory law in Germany, relating to the entire German population from which this great army is enlisted was not enacted till 1874, and from that day to the present there has been only one death from small-pox in the German Army.

Moreover the writer persistently ignores the most convincing argument in favor of vaccination, that is, the position of the entire German population in its comparative immunity from small-pox. Almost the only deaths which have occurred from this cause in Germany in the past quarter of a century are either those of foreigners who have crossed the border from partially vaccinated countries like Russia, Austria and France, after exposure at home, or of infants in the first year of life, who had been attacked before the legal age-limit for vaccination had expired.

It is refreshing to turn from such mischievous works as this volume to read the following declaration from the late Secretary of the Massachusetts State Board of Health, Dr. Geo. Derby.[1] It was written in 1871, and is as true at the present day as when first published.

"We may speculate about the potency of vaccine being exhausted in the human family, we may be surprised to find that people with good vaccine scars sometimes have small-pox, we may dispute as much as we please about the average period when re-vaccination may be considered a prudent safeguard . . . we may turn the vaccination question with ingenious skill, so that its many facets shall reflect a multitude of curious lights, and after all we find that we rest in a security against this most horrid pestilence unknown to former generations."

Laboratory Work in Bacteriology. By FREDERICK G. NOVY, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry of the University of Michigan. Second edition. Ann Arbor: George Wahr. 1899.

A Manual of Bacteriology. By HERBERT U. WILLIAMS, M.D., Professor of Pathology and Bacteriology, Medical Department of the University of Buffalo. Philadelphia: P. Blakiston, Son & Co. 1898.

Neither of these books deserves special notice. Their publication would seem to be due to the desire of these professors to provide a special text-book for their students. They are probably well adapted for this purpose, but they are inferior to other well-known works on bacteriology, and are not adapted for general use.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 27, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE TENTH ANNIVERSARY OF CLARK UNIVERSITY.

THE recent celebration of the tenth anniversary of the founding of Clark University at Worcester was rendered notable by the presence of a number of distinguished European scholars, among whom were three physicians to whom modern medical research owes much. These were Prof. Angelo Mosso, of the University of Turin, Prof. August Forel, of Zürich, and Prof. Santiago Ramón y Cajal, of Madrid. Each of them stands foremost in his special line of work, and those who were invited to attend their lectures must have come away with a deepened sense of the significance of research, both in its practical and theoretic aspects.

Mosso spoke on one of his favorite topics, namely, the relation of physical to mental development in the growing child. No doubt to many of his hearers his point of view seemed extreme in his insistence on the postponement of the rudiments of mental training to a relatively late period of the child's life, but no one could question the essential correctness of a theory which maintains the importance of a correct muscular training as a substratum for future mental development. It is an idea which is gradually, but surely, creeping into our educational systems, and one which is surely destined to result ultimately in increased mental efficiency.

Forel discussed certain phenomena of suggestion, and added the weight of his undisputed authority to the value of a mental treatment of a large class of ailments, a matter which all signs go to show must soon be taken up seriously and earnestly by the profession at large. We should cordially welcome all attempts made by men of broad training and scientific instincts toward a solution of what is sure to prove a therapeutic problem of great subtlety and extreme significance. As is well known, Forel has for many years been a recognized authority on "ants," as well as on man, and he also spoke at the meeting in question on certain of their habits and attributes.

About Ramón y Cajal centres a very peculiar and special interest. He represents a nation not noted for its medical scholars, and one to whom we have not in the past looked for scientific progress. He stands, therefore, almost alone among his people in his distinction of being the greatest living authority on many matters relating to the cerebral cortex. It is to him we owe the brilliant application of the Golgi method to the problems of nerve anatomy and a clear recognition of its significant implications, which have rendered possible our modern conception of the architecture of the nervous system. He spoke of his recent work on certain nerve cells.

At the conclusion of the series of lectures, which extended over several days, the honorary degree of LL.D. was conferred, among others, upon each of the physicians to whom we have alluded, a matter of added interest, inasmuch as the degree had not before been given by the University.

THE PRIVATE DISPENSARY.

THE establishment of a private free dispensary in Chicago has given rise to the query in certain quarters as to whether such an innovation is consistent with American ideas of medical education and medical charity. It is claimed that private dispensaries will tend merely to increase the abuses which already exist, and about which so much has of late been said and written. The more opportunities the poor are granted to have their ills cared for free of charge, the more will they avail themselves of the privileges offered, to the detriment of those physicians who would welcome a fee, however small. It may also with reason be said that any greater hospital privileges will tend to decrease still more that self-respect which is already lacking to an alarming degree among the lower classes in our large cities. Whatever else happens, it is the duty of physicians, as good citizens, not to pauperize the community for any personal reason. Apart, also, from any moral question involved, it may be said that we already have enough dispensaries and to spare, which are quite able to care in the best possible way for the deserving poor.

In view of these arguments, which surely should carry weight, it is of interest to see if there is any other side to the question. As we know, for many years private dispensaries have been established, and are recognized, throughout Germany, and in them much admirable teaching and brilliant research are done. These *polyclinics* are for the most part conducted by men of ability and enthusiasm, who have failed for some reason to attain a hospital connection. The clinics are unassuming in outward appearance and make no special inducements to patients beyond the reputation of their conductors. Evidently such dispensaries subserve a double purpose, first, as centres at which disease may be systematically studied, and, secondly, where teaching may be done, often to excellent advantage. These are both, certainly, entirely worthy motives.

To a man who is bent on clinical research, and who thinks, also, he has a mission as a teacher, it would appear unfair that he be completely cut off from his ambitions by the fact that he can find no place at one of the established hospitals or dispensaries. To our mind there is no inherent reason why a multiplication of dispensaries should be an evil, provided only the motives for their establishment are worthy, and a rigid watch be kept against the abuse of privileges by their patrons. The moment such dispensaries were carried on recklessly or for unworthy and mercenary ends we might expect that public opinion would quickly lead to their abolition. In the meantime, however, we see no reason to discourage any measures which are likely to lead to the more accurate study of disease, and to the dissemination of knowledge regarding it. We need certainly to keep before our minds the ideals which have been set us by Germany. In that case we permit ourselves to hope there would be small risk of abuse.

ENGLISH *VS.* AMERICAN ATHLETES.

It is of interest to note that in the recent athletic contest between the representatives of English and American universities, the Englishmen won those events which called for physical endurance, whereas the Americans were successful in the contests requiring special strength and skill, without prolonged muscular effort. In no case did the Americans win, or come very near winning, any of the long runs, whereas in short distances, the one-hundred-yard dash, for example, a supreme effort in the last few yards brought the American representative in ahead of his English competitor. The hurdle race also, requiring much skill, combined with temporary effort, was easily won by an American. The result of the longer runs might have been different, had the man upon whom the Americans depended not been somewhat out of condition, but the fact remains that the English athletes had an endurance which was entirely lacking in our men. Whether this resulted from different training or climatic conditions, or some more subtle cause, it is quite impossible to say, and certainly the data are as yet too few upon which to base conclusions. It is, however, to be hoped that this meeting, with a result so creditable to both sides, may be repeated each year alternately on this and on the other side of the Atlantic, and that an opportunity may thus be given, extending over a considerable period, of comparing methods of training and determining whether or not racial peculiarities or climatic differences underlie the rather striking outcome which we have had occasion to note this year. Some years ago a team of amateur English athletes visited this country, and were thoroughly beaten. On that occasion they encountered, in addition to their opponents, excessively hot weather, which no doubt was a factor in the result. It is generally recognized, moreover, that a visiting team is always at a disadvantage.

MEDICAL NOTES.

A Polyclinic in London. — A polyclinic has been established in London, which it is hoped will make the teaching facilities of that city more available than they have been in the past.

Yellow Fever Declining at Santiago. — It is gratifying to learn that the vigorous measures inaugurated by General Wood on his return have resulted in a rapid decline in yellow fever at Santiago, and the United States troops were reported free from it a week or more ago.

Hospitals as a Field for Christian Scientists. — We learn from the *Medical News* that in some inexplicable way a man who claimed to be a Christian Scientist, an "Eddyite" or "Divine Healer," and able to cure every disease afflicting the patients, got into Bellevue Hospital one day last week. He told the patients that the attendant physicians at the hospital were their worst enemies, and were merely experimenting on them for the benefit of the higher classes. The man had elaborately printed cards, on the back of which were crosses in red, and "P. J. Durvin, 285 Bowery," also the announcement that he and the Saviour were able to cure every manner of disease. Durvin succeeded in passing through several of the wards before he was interrupted. It is said that he then left the hospital by the "most direct route." The patients were all more or less excited over the visit.

The Microbe and the Passenger. — The Paris correspondent of the *Lancet* states that a Parisian who was lately travelling by train refused to show his ticket to a travelling inspector of the company. The passenger was accordingly summoned by the company for refusing to show his ticket, as he was bound to do by law. He argued, however, that he had not refused to show it (*présenter*), that he had let the inspector see it so that he could easily satisfy himself as to its being in order, but that he certainly had refused to let the ticket inspector take it into his hands because his hands were so dirty. He, the passenger, therefore, was unwilling to put into his pocket a ticket which would be contaminated with microbes and might very likely give him some disease. After a long legal discussion as to the exact meaning of the word "show" (*présenter*), the court fined the ardent disciple of modern hygiene the sum of one franc. — *Journal of the American Medical Association.*

The Cultivation of the Bacillus Lepræ. — At a recent meeting of the National Academy of Medicine of Bogota Dr. Carrasquilla asserted that he had successfully cultivated the bacillus lepræ on sloped solidified human serum and on beef bouillon prepared according to the method of Thoinot and Masselin. The bacillus was then cultivated from serum to serum, and from bouillon to bouillon, pure cultures being always obtained. Dr. Carrasquilla further states that he observed the bacillus in motion in two stages of its development — as long, slender

bacilli, which move in an undulatory manner; and as short, coarse, almost elliptical bodies moving rapidly in a straight line. In the latter he fancies he has observed flagella, but he is not positive as to this. His results do not entirely accord with those obtained by Professor Spronck, of Utrecht, who has also claimed to have cultivated Hansen's bacillus. Professor Campana, of Rome, has also convinced himself that he has successfully cultivated the bacillus leprae. These experiments require confirmation and extended observation before they can be accepted as absolute. — *British Medical Journal.*

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 26, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 48, scarlet fever 13, measles 34, typhoid fever 21.

TYPHOID EPIDEMIC TRACED TO MILK. — A small epidemic of typhoid fever, which has been traced to a milk route is reported in Jamaica Plain, Mass.

TWO MORE CASES OF TETANUS. — A boy of eleven years died at Woonsocket, R. I., on July 24th from tetanus, caused by a blank-cartridge wound received on July 1st. The ten-year-old son of Rev. G. H. Horton, of Blackstone, is ill with tetanus due to the same cause.

NEW YORK.

BEQUESTS TO HOSPITALS. — Martin H. Lehmaier, who died last month, bequeathed $2,500 to Mount Sinai Hospital for the founding of a bed in his memory. By the will of Daniel Krakauer $2,000 is left to Mount Sinai Hospital and $1,000 each to the Montefiore Home for Chronic Invalids and several other Hebrew charitable institutions.

A LARGE FEE FOR VISITS. — The newspapers report that a case is pending in the Supreme Court of Tompkins County, New York, in which Dr. H. L Robinson, of McLean, is suing G. E. Chambers, of the same village, for a bill of $10,000 for professional services consisting of ten visits during a recent illness. If the rest of the doctor's practice pays him these rates he ought to be able to keep the wolf from the door.

VACATION SCHOOLS POPULAR. — The second season of vacation work in the public schools of Manhattan and Bronx Boroughs was begun on July 18th, and the number of children applying for admission was much larger than could be accommodated, as the appropriation for the total expense is limited to $30,000. There are ten schools, divided into kindergarten, primary, grammar, art and industrial schools, with three hours' daily sessions. For the girls there are practical courses in domestic economy, cooking, housecleaning, dressmaking, nursing and the hygiene of the sick-room, and for the boys, in various branches of mechanical industry. The indoor gymnasiums used last year have been supplemented this year with five outdoor gymnasiums, and other features that have been added this season are swimming lessons in the city's free baths and sketching classes in the parks. The vacation-school system has this year been introduced for the first time in Brooklyn, and there are now six schools in operation there under the direction of the Borough School Board.

A CASE OF ACROMEGALIA. — A remarkable case of acromegalia, said to be the first one of that disease recorded at the institution, was received in Bellevue Hospital on July 20th. The patient was an elderly woman six feet in height, and her head, nose and extremities were enormously enlarged, while a heavy gray moustache and beard gave her a most formidable appearance. She was in a state of exhaustion when admitted, and died on the following day.

WOMEN NURSES START FOR THE PHILLIPINES. — Nine women nurses, six of them graduates of New York training schools, and the others graduates of schools in Boston and New Haven, started for the Philippines on July 20th. They were sent in response to an appeal for more nurses recently cabled from Manila, and went under the auspices of a ladies' organization for the maintenance of trained nurses formed during the recent war. At Manila they will report to Miss Henshall, who is at the head of the eighteen trained nurses already sent out by the same society.

THE BABIES' HOSPITAL, SEASIDE BRANCH. — The new building of the seaside branch of the Babies' Hospital, an adjunct of the Post-Graduate Medical School and Hospital, was opened at Oceanic, N. J., on July 21st. A special feature of it is accommodations for pay patients, where the infants of well-to-do parents may be sent for treatment.

THE HARPER PAVILION. — The new wing of the Monmouth Memorial Hospital, at Long Branch, N. J., which has been erected at a cost of $10,000 and is to be known as the Harper Pavilion, was dedicated with appropriate ceremonies on July 18th.

MORE DEATHS FROM TETANUS. — During the week ending July 22d there were reported two deaths from tetanus, the result of Fourth of July accidents, in New York, and one each in Yonkers, Syracuse, Paterson, N. J., Elizabeth, N. J., and Passaic, N. J. In all the cases except one it is stated that antitoxin serum was employed. The deaths in Yonkers and Passaic were both in patients which last week were reported as improved under the serum treatment. Four deaths in all have occurred at Yonkers and three at Syracuse.

ARMY NOTES.

THE ARMY RATION. — Dr. L. L. Seaman, of New York, late surgeon of the First Regiment, U. S. Volunteer Engineers, who is now on a visit to the Philippines in a semi-official capacity, has offered, through the Military Service Institution of the United States, a prize of $100, or a gold medal of that value,

if preferred, for the best essay on "The Ideal Ration for an Army in the Tropics." The Executive Council of the Military Service Institution, at a meeting recently held at its headquarters on Governor's Island, adopted a resolution of thanks to Dr. Seaman and decided that all essays offered in competition should be submitted by March 1, 1900, to a committee of award consisting of Colonel Weston, Acting Commissary-General, Lieut.-Col. Charles Smart, Deputy Surgeon-General, and Lieutenant-Colonel Dougherty, Seventh U. S. Infantry.

Care of Orphans in Cuba. — Miss Clara Barton, President of the National Red Cross Society, who arrived from Havana on July 20th, reports that during the past three months the Society has organized in Cuba twelve asylums for reconcentrado orphans, in which there are now accommodated about twelve hundred children of from three to fifteen years of age.

Transportation of the Wounded in the Philippines, Health of the Troops, etc. — In a report just received from Manila covering the month of May, the movements of the medical department attached to the 2d Division, 8th Army Corps, are detailed by Major Henry F. Hoyt, chief surgeon of that division. As the movements north of the Rio Grande River were along the line of the railroad, hand-cars were found to be of much service in the transportation of hospital supplies and wounded. In anticipation of the fight of May 3d, four ambulances were taken across the river on a raft, the bridge having been destroyed. These ambulances were of great value in the action which commenced at about the time of their arrival. The wounded were brought by them to the railroad and transported on hand-cars to the broken railroad bridge, where they were transferred to litters, ferried across the river on two cascoes lashed together, and were again placed on the hand-cars. The hospital-corps men suffered considerably from heat and exhaustion, and Filipino prisoners were impressed to propel the hand-cars. At Bagbag the wounded were transferred to steam-cars and sent into Manila. On May 6th the remaining ambulances succeeded in crossing the river and a temporary hospital was established in several large houses in San Fernando. On May 12th Major Hoyt made an inspection of the troops of the command and found them much exhausted and debilitated by the hardships of the campaign in which they had engaged. Diarrheal troubles appeared to be on the increase in the command, and regulations were issued providing for the restriction of the purchase and use of fruits by the men. In response to a request for suggestions as to improvement in the existing ration, Major Hoyt advised that a daily issue of six ounces of rice per man be authorized and that its use be encouraged by company officers. Instead of canned corned beef, which he said was universally condemned during the present campaign, he advised the use of a sausage containing five parts of beef and one of pork and the issue of a canned vegetable soup in lieu of the allowance of beans. On the 24th an engagement west of San Fernando took place, the wounded being sent in on ambulances, cared for at the hospital and shipped to Manila by train. On the 25th five buildings were selected in San Fernando and a division field hospital established therein, the first in the Philippine war. It had a capacity at the outset of 200 beds, Major Guy L. Edie being assigned in charge. At the end of the month the troops were found debilitated and exhausted from the hardships which they had undergone and it was noticed that recuperation seemed to be slow. During the month, in the seven regiments composing the division, the casualties were six killed and 52 wounded, or a mortality of ten per cent. in the total number of hits. With this division there were serving 27 medical officers, 19 hospital stewards, 17 acting hospital stewards, 110 privates of the hospital corps, 9 ambulances and 78 coolie litter-bearers. With regard to the latter, Major Hoyt says, that as litter-bearers they are very satisfactory but do not prove efficient workers in connection with the hospitals. Their employment in the field is of much assistance, since it leaves the trained man of the hospital corps free for other more important duties.

Hospital Ships and Army Transports. — The hospital ship *Missouri* is now at Brooklyn, undergoing extensive repairs and alterations preparatory to her voyage to Manila, where she will hereafter be stationed. The trip will be made *via* the Suez Canal and the ship is expected to be in readiness to start about August 20th. The medical department in the Philippines will be well supplied with floating-hospital facilities on her arrival. The *Missouri* and *Relief* together have ample accommodations for more than 500 patients. Each army transport possesses a well-appointed hospital of a size proportionate to the carrying capacity of the ship, and returning transports carrying no troops have been found of excellent service, after special preparation, in the transfer of convalescent patients to the United States.

Miscellany.

THE SEXUAL DIFFERENCES OF THE FETAL PELVIS.

While the existence of structual differences between the pelves of the male and female adult has long been recognized, the source and method of production of these differences are problems which have occupied the attention of many generations of obstetricians and anatomists. It has generally been assumed that the characteristic features of the female pelvis do not take shape until the period of puberty, and an immense amount of ingenuity has been expended in providing hypothetical explanations of the change. Matthews Duncan, for example, held that the special features of the male pelvis were due to the

bones being thicker, stronger, and stouter than in the female, a further factor being their supposed earlier consolidation with each other. This, however, is more of the nature of a statement of appearances than an explanation of their causation, and this observer's theory of the action of natural, that is, muscular, forces, falls to the ground in view of the fact that such forces must act similarly if not quite to the same extent, in both sexes. The obscurity which has hitherto surrounded the production of these differences has to a large extent been cleared away by the painstaking investigations of Professor Thomson, of Oxford, who, in a demonstration at the last meeting of the Obstetrical Society, showed clearly enough, by the aid of numerous beautiful specimens of fetal pelves, that the distinguishing features which serve to identify the pelvis of the male and female respectively are quite well marked as early as the third month of intra-uterine life. It is highly probable, and by no means inconsistent with biology, that these differences exist *ab initio*, though this obviously cannot be affirmed, owing to the fact that at an earlier date the identification of sex is not possible. None, however, can doubt that a fetus is male or female from the very b ginning, though evidence thereof is not as yet available, and it follows that if we could only check the observations the same differences would probably be met with coincidently with the formation of the pelvis as a definite structure. This important contribution marks an epoch in our knowledge of the development of the fetus and will greatly simplify the proper comprehension of the subject. — *Medical Press and Circular.*

A NEW PATHOGENIC MICROBE OF SEWAGE.

THE following account of a new pathogenic microbe, which has been isolated by Dr. E. Klein, and named by him the *Bacillus Pyogenes Cloacinus*, is given in the *British Medical Journal* for July 8th:

This microbe was isolated in pure culture from the purulent peritoneal and pleural exudations of a guinea-pig that died forty-eight hours after subcutaneous injection of a small amount of the deposit of fresh sewage; also from the subcutaneous abscess of this and the companion guinea-pig injected at the same time. The above purulent exudations, as also the pus of the abscess, were crowded with the microbe, either free in the fluid or enclosed in groups within the substance of the pus cells.

The microbe is a minute bacillus, the average length varying between 0.6μ and 1.25μ (few are longer), cylindrical, and in chains; its thickness is about 0.4μ. It is non-motile and stains slightly in Gram.

In gelatine plates kept at 20° to 21° C. the first traces of growth show themselves after forty-eight hours in the form of gray translucent round dots; these enlarge slowly, forming circular flat discs, slightly thicker in the centre than at the margin.

In gelatine streak the growth is gray, translucent; when growth is complete, say, after two to three weeks, it shows under a magnifying glass a thicker knobby centre and a thin translucent margin.

In gelatine stab the track of the needle becomes marked as a thin whitish line, which under a magnifying glass is seen composed of closely-placed minute droplets; on the surface of the stab a circumscribed flat gray expansion is just noticeable with the unaided eye. The gelatine is not liquefied after weeks and months. On the agar surface the colonies are translucent gray, moist, viscid discs; in agar streak translucent gray, viscid bands; in agar stab (37 C.) the growth is like that in gelatine stab, except that at the surface of the stab there is a circular, distinct, plate-like expansion of the growth.

In alkaline beef broth kept at 37° C. the growth is rapid; the broth is slightly turbid already after twenty-four hours, but after several days the broth clears and shows numerous fine granules along the sides and a powdery precipitate at the bottom of the tube. The broth, even after growth is completed, has a distinctly alkaline reaction; no indol is produced. The microbe grows well in litmus milk and in milk without altering either the litmus or the fluid condition, reaction, and aspect of the milk.

In shake culture in ordinary gelatine or in grape sugar gelatine it produces no gas; it grows very feebly in the depth of the gelatine. On potato no growth is visible or demonstrable by microscopic specimens. The microbe does not grow on acid media, and in fluid media distinctly produces alkali. Neither the pus of the abscess nor the purulent exudations, nor any of the cultures, have any smell.

The microbe, when injected in minute doses, is pathogenic. Small doses — even a portion of one colony — cause disease in the guinea-pig. When injected subcutaneously into the groin, in the majority of instances only a local abscess is the result; this commences as a small tumor a day or two after the injection; this enlarges, and soon becomes changed in the course of two or three days into an abscess, from the size of a bean to that of a hazel nut, filled with creamy thick pus. Under the microscope the fluid contains an abundance of the bacilli as single individuals, or more frequently as dumb-bells; some few are cylindrical and some in chains. Many of the pus cells contain the bacilli, occasionally their protoplasm being packed with the bacilli. Some pus cells are greatly swollen by the number of bacilli, and eventually disintegrate, so that the groups and clumps of the bacilli become free. In a large minority of instances, however, the result of subcutaneous injection is, besides the local abscess, general disease, ending fatally in three to four days.

When the result of inoculation is a local abscess only, no bacilli can be found in the blood, but when it is a general purulent inflammation of the serous membranes, the blood of the heart and of the viscera, spleen particularly, contains an abundance of the microbe.

Injection of minute doses into the peritoneal cavity of guinea-pigs leads to fatal result within twenty to twenty-four hours. On post-mortem examination purulent peritonitis, with pyogenic membranes on the liver, spleen, diaphragm and kidney, and inflammation of the small intestine, occasionally pleural and pericardial exudation, are also present.

In the mouse subcutaneous injection of the culture in small doses causes general septicemic infection, the blood of the heart and of the viscera teeming with the microbe, the viscera of the abdomen and thorax being greatly congested.

In the rabbit no pathogenic effect is produced.

From these observations, both as to cultural characters and as to the result of animal experiments, it is clear that the microbe is distinct from Passet's bacillus pyogenes fetidus, as also from Bolton's bacillus pyogenes soli. Culturally it resembles, to a certain extent, the bacillus suisepticus (German *Schweineseuche*) of Löffler and Schütz, but the action of this latter on rodents is altogether of a different nature from that described above of our microbe. On account of its derivation from sewage and its conspicuous pyogenic action, Klein proposes for it the name "bacillus pyogenes cloacinus."

THERAPEUTIC NOTES.

DR. KARL HEXHEIMER treated twenty-eight cases of psoriasis with intravenous injections of arsenic, and obtained cures even in cases in which no local treatment was applied. The cure was usually evident by

the end of the second or the beginning of the third week, by which time the papules became darker, and the crusts diminished, when finally the pigmentation would disappear altogether. The average duration of the treatment was about forty-eight days. The initial dose of the arsenious acid was $\frac{1}{10}$ grain, which was increased daily by $\frac{1}{10}$ until $\frac{1}{5}$ grain was reached, this last remaining until the final disappearance of the efflorescence. The injections were mostly made into the elbow-joints, the forearm being compressed with an Esmarch bandage, which made the veins very prominent. To prevent any recurrence, the author recommends intermittent treatment, similar to what is done in syphilis, during the periods free from symptoms.[1] We think, however, that the dose of arsenic is much too large.

FOR SPASMODIC CROUP:[2]

℞ Nitroglycerin . . . . . gttm 1-10-1-15
Spir. vini gallici . . . . . ʒiv
M. Et sig. Two to five drops every two to three hours in some sweetened water.

FOR VOMITING OF SEA-SICKNESS:[3]

℞ Menthol . . . . . gr. ii
Cocainæ hydrochl. . . . . gr. iii
Syr. simpl. . . . . ʒi
Spir. vini rectif . . . . . ʒii
M. Et sig. A teaspoonful every hour.

Obituary.

RUSSELL STURGIS, JR., M.D.

DR. RUSSELL STURGIS was born on December 16, 1856. He was prepared for college at St. Paul's School, Concord, N. H., and received the degree of A.B. as a member of the class of 1878, Harvard College. He took the degree of M.D. (Harvard) in 1881. On March 30, 1880, he was married to Anne Outram Bangs.

In the latter part of May Dr. Sturgis was taken with typhoid fever in a severe form. He did well, however, for the first two or three weeks, when an extensive infarction of the right lung occurred. From this time he grew gradually weaker, though an occasional rally gave ground for hope. He finally succumbed on July 17th, after an illness which he bore with great fortitude. Mrs. Sturgis, a son and six daughters survive him.

Dr. Sturgis's death was a profound shock to a wide circle of patients and friends. He was loyal, devoted, warm-hearted and self-sacrificing. These qualities, which won the respect, gratitude and affection of all who knew him, are now recalled with a sharp sense of personal bereavement.

The professional labors of Dr. Sturgis were at first devoted more especially to the diseases of children. Later he became interested in nervous diseases and the phenomena of hypnotism. After considerable experience in those nervous diseases marked by a "fixed idea" he published a paper of great interest and importance on "The Use of Hypnotism to the First Degree as a Means of Modifying or Completely Eliminating a Fixed Idea." This contribution contained original and valuable observations, which attracted wide notice. His success in the personal treatment of these obstinate cases led to the publication in 1899 of a second paper on the same subject. The methods used by Dr. Sturgis were painstaking; the cases themselves were from their nature trying; his results were often brilliant. It is a matter of deep regret that the work so auspiciously begun, so full of promise for future development, should have been thus early interrupted.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 20, 1899.

BAILHACHE, PRESTON H., surgeon. To proceed to New York, N. Y., for special temporary duty in the Purveying Depot. July 20, 1899.

BANKS, C. E., surgeon. Relieved from duty at Washington, D. C., and detailed as medical purveyor of the Service at New York, N. Y. July 17, 1899.

GEDDINGS, H. D., passed assistant surgeon. To proceed to New York, N. Y., for special temporary duty. July 15, 1899.

ROSENAU, M. J., passed assistant surgeon. Detailed as inspecting quarantine officer for the island of Cuba. July 19, 1899.

FRICKS, L. D., assistant surgeon. To proceed to the Brunswick Quarantine Station, Brunswick, Ga., for special temporary duty. July 18, 1899.

MCADAM, W. R., assistant surgeon. Granted seven days' extension of leave of absence. July 18, 1899.

RICHARDSON, T. F., assistant surgeon. Relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Cienfuegos, Cuba, for temporary duty. July 17, 1899.

THORNBURY, F. J., assistant surgeon. To proceed to Point Pleasant, N. J., for special temporary duty. July 18, 1899.

BURFORD, R. E. L., sanitary inspector. Granted leave of absence for seven days. July 18, 1899.

APPOINTMENT.

ALANSON WEEKS, of Michigan, to be acting assistant surgeon, for duty at the port of Chicago, Ill. July 13, 1899.

RECENT DEATHS.

CYRUS N. CHAMBERLAIN, M.D., M.M.S.S., died at Jamaica Plain on July 18th, at the age of seventy years. He was an active and efficient surgeon in the U. S. Army during the Civil War and organized a general hospital at Gettysburg after the battle, and the Dale General Hospital at Worcester, Mass. He retired from the army in 1865 with the rank of lieutenant-colonel, received for meritorious service. In 1865 he went to Lawrence, Mass., where he built up a large practice. He has been a councillor of the Massachusetts Medical Society and was twice president of the Essex North District Medical Society. He was visiting physician and later consulting physician to the Lawrence Hospital. He retired from practice and went to Andover to live a few years ago. His death ended an active and useful professional career.

JAMES S. GEARY, M.D., for two years a coroner's physician in the Borough of the Bronx, died at the age of thirty, on July 17th, of pulmonary tuberculosis. He was educated at St. John's College, Fordham, and graduated from Bellevue Hospital Medical College in 1892, and he afterwards served on the house staff of St. Francis' Hospital.

J. WILLIAM NIEDECKER, M.D., of Brooklyn, died suddenly of apoplexy, on July 17th, at the age of thirty-eight. He was born in Cleveland, O., and was a graduate of the Columbus Medical College and the Long Island College Hospital.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Medical Society of the State of North Carolina, Forty-fifth Annual Meeting, held at Charlotte, N. C., May 3, 4 and 5, 1898.

Addresses and Papers by the Members of the Instructing Staff of the New York State Veterinary College for the years 1896-98. Ithaca, N. Y. 1898.

The Serum Diagnosis of Disease. By Richard C. Cabot, M.D., Physician to Out-patients, Massachusetts General Hospital. New York: William Wood & Co. 1899.

Essays for Students. By Stephen Paget, F.R.C.S., Surgeon to the West London Hospital; Surgeon to the Ear and Throat Department of the Middlesex Hospital. New York: William Wood & Co. 1899.

Transactions of the New York State Medical Association for the year 1898. Volume XV. Edited for the Association by M. C. O'Brien, M.D., of New York County. New York City: Published by the Association.

Elementary Physiology. By Benjamin Moore, M.A., Professor of Physiology in the Medical Department of Yale University, etc. With 125 illustrations. New York, London and Bombay: Longmans, Green & Co. 1899.

Golden Rules of Gynæcology. By S. Jervois Aarons, M.D., Registrar to the Hospital for Women, Soho, etc. "Golden Rules" Series, No. II. Bristol: John Wright & Co. Loudon: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1898.

Our Baby: for Mothers and Nurses. By Mrs. Langton Herver, Diplomée Obstetrical Society, London; late Hospital Ward Sister; author of "Antiseptics: a Hand-book for Nurses." Sixth edition, revised. Bristol: John Wright & Co. 1899.

Respiratory Exercises in the Treatment of Diseases, Notably of the Heart, Lungs, Nervous and Digestive Systems. By Harry Campbell, M.D., B.S. (Lond.), Fellow of the Royal College of Physicians, London, etc. New York: William Wood & Co. 1899.

The Treatment of Disease by Physical Methods. By Thomas Stretch Dowse, M.D. (Abd.), F.R.C.P. (Edin.), formerly Physician-Superintendent, Central London Sick Asylum; President North London Medical Society, etc. New York: E. B. Treat & Co. 1899.

Surgical Nursing. By Bertha M. Voswinkel, Graduate of Episcopal Hospital, Philadelphia; late Nurse-in-charge of Children's Hospital, Columbus, O. Second edition, revised and enlarged, with 112 illustrations. Philadelphia: P. Blakiston, Son & Co. 1899.

On the Study of the Hand for Indication of Local and General Disease. By Edward Blake, M.D., M.R.C.S., Life Associate, Sanitary Institute Great Britain; Foundation Fellow British Gynecological Society, etc. Second edition. London: Henry J. Glaisher. 1899.

Cyclopedia of the Diseases of Children, Medical and Surgical. The articles written especially for the work by American, British and Canadian authors. Vol. V, Supplement. Edited by William A. Edwards, M.D. Illustrated. Philadelphia: J. B. Lippincott Co. 1899.

American Association for the Advancement of Science: Preliminary Announcement of the Forty-eighth Annual Meeting to be held at Columbus, O., August 21 to 26, 1899, and of the meetings of Several Affiliated Scientific Societies that will hold their Sessions in Columbus. 1899.

International Clinics: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, etc. Edited by Judson Deland, M.D., J. Mitchell Bruce, M.D., F.R.C.P., and David W. Finlay, M.D., F.R.C.P. Volume IV. Eighth series. 1899. Philadelphia: J. B. Lippincott Co. 1899.

Three Practical Points in the Management of Fractures at the Elbow-joint. I. General Considerations upon Major Anesthesia. II. Threatened Death during Major Anesthesia. III. A Brief Digression upon Shock. Shock. By Robert H. M. Dawbarn, M.D., New York. Reprints. 1897-99.

Twentieth Century Practice, an International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In twenty volumes. Vol. XVI. Infectious Diseases. New York: William Wood & Co. 1899.

The Influence of Character and Right Judgment in Medicine: The Harveian Oration delivered before the Royal College of Physicians, October 18, 1898. By Sir Dyce Duckworth, M.D., LL.D., Fellow and Treasurer of the College, etc. New York and Bombay: Longmans, Green & Co. 1898.

A Compend of Human Physiology, Especially Adapted for the Use of Medical Students. By Albert P. Brubaker, A.M., M.D., Adjunct Professor of Physiology and Hygiene in the Jefferson Medical College, etc. Ninth edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co. 1899.

Thirtieth Annual Report Relating to the Registry and Returns of Births, Marriages and Deaths in Michigan for the year 1898. By the Secretary of State of Michigan. Edited by Cressy L. Wilbur, M.D., Chief of the Division of Vital Statistics. By authority, Lansing: Printed by the State. 1898.

Notes on Surgery for Nurses. By Joseph Bell, M.D., F.R.C.S. (Edin.), Consulting Surgeon to the Royal Infirmary and to the Royal Edinburgh Hospital for Sick Children. Fifth edition, thoroughly revised. Edinburgh: Oliver & Boyd. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1899.

Treatise on Human Physiology, for the use of Students and Practitioners of Medicine. By Henry C. Chapman, M.D., Professor of Institutes of Medicine and Medical Jurisprudence in Jefferson Medical College, Philadelphia, etc. Second edition, illustrated with 595 engravings. Philadelphia: Lea Brothers & Co. 1899.

The Newer Remedies: A Reference Manual for Physicians, Pharmacists and Students. By Virgil Coblentz, A.M., Phar.M., Ph.D., F.C.S., etc. Professor of Chemistry and Physics in the New York College of Pharmacy, etc. Third edition, revised and very much enlarged. Philadelphia: P. Blakiston, Son & Co. 1899.

A Treatise on Fractures and Dislocations, for Practitioners and Students. By Lewis A. Stimson, B.A., M.D., Professor of Surgery in Cornell University Medical College, New York. In one octavo volume of 823 pages, with 321 engravings and 20 full-page plates. Philadelphia and New York: Lea Brothers & Co. 1899.

An Experimental Research into Surgical Shock. An essay awarded the Cartwright Prize for 1897. By George W. Crile, A.M., M.D., Ph.D., Professor of the Principles of Surgery and Applied Anatomy in the Cleveland College of Physicians and Surgeons, etc. One hundred and sixty pages. Philadelphia: J. B. Lippincott Co.

The Philosophy of Memory and Other Essays, Consisting of articles on the Philosophy of Emphasis; The Functions of the Fluid Wedge; The Birth of a Planet; The Laws of Riverflow. By D. T. Smith, M.D., Lecturer on Medical Jurisprudence in the University of Louisville. Louisville, Ky.: Press of John P. Morton & Co. 1898.

Golden Rules of Surgical Practice. By E. Hurry Fenwick, F.R.C.S., Surgeon to and Lecturer on Clinical Surgery at the London Hospital, etc. "Golden Rules" Series, No. I. Fifth edition, revised and enlarged. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. Hirschfeld Bros. 1898.

Diagnosis by the Urine, or the Practical Examination of Urine, with Special Reference to Diagnosis. By Allard Memminger, M.D., Professor of Chemistry, Urinology and Hygiene in the Medical College of the State of South Carolina, etc. Second edition, enlarged and revised, with illustrations. Philadelphia: P. Blakiston, Son & Co. 1899.

Railway Surgery: A Hand-book on the Management of Injuries. By Clinton B. Herrick, M.D., Troy, N. Y., Lecturer on Clinical Surgery, Albany Medical College; Attending Surgeon to the Troy Hospital and to the House of the Good Shepherd, etc. Profusely illustrated by numerous original engravings. New York: Wm. Wood & Co. 1899.

Clinical Lectures on Neurasthenia. By Thomas D. Savill, M.D., Physician to the West End Hospital for Diseases of the Nervous System, London; Examiner in Medicine to the University of Glasgow; formerly Medical Superintendent of the Paddington Infirmary and Assistant Physician to the West London Hospital, etc. London: Henry J. Glaisher. 1899.

On Varix: Its Causes and Treatment, with Especial Reference to Thrombosis. An address delivered at the inaugural meeting of the Nottingham Medico-Chirurgical Society, Session 1898-99. By William H. Bennett, F.R.C.S. (Eng.), Surgeon to St. George's Hospital and Joint Lecturer on Surgery at the Medical School, etc. New York and Bombay: Longmans, Green & Co. 1899.

An American Text-book of Diseases of the Eye, Ear, Nose and Throat. Edited by G. E. de Schweinitz, A. M., M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia, etc., and B. Alex. Randall, M.A., M.D., Ph.D., Clinical Professor of Diseases of the Ear in the University of Pennsylvania, etc. Illustrated with 766 engravings. Philadelphia: W. B. Saunders. 1899.

Fever Nursing, designed for the Use of Professional and Other Nurses, and Especially as a Text-book for Nurses in Training. By J. C. Wilson, A.M., M.D., Author of "A Treatise on the Continued Fevers," Visiting Physician to the Hospital of the Jefferson College and the Pennsylvania Hospital, etc. Third edition, revised and enlarged. Philadelphia and London: J. B. Lippincott Co. 1899.

An Essay on the Nature and the Consequences of Anomalies of Refraction. By F. C. Donders, M.D., late Professor of Physiology and Ophthalmology in the University of Utrecht. Revised and edited by Charles A. Oliver, A.M., M.D. (Univ. Pa.), one of the Attending Surgeons to the Wills Eye Hospital, etc. With portrait and other illustrations. Philadelphia: P. Blakiston, Son & Co. 1899.

Practical Materia Medica for Nurses, with an Appendix containing Poisons and their Antidotes, with Poison-emergencies; Mineral Waters; Weights and Measures; Dose-list, and a Glossary of the Terms used in Materia Medica and Therapeutics. By Emily A. M. Stoney, Graduate of the Training School for Nurses, Lawrence, Mass.; late Head-nurse, Mercy Hospital, Chicago, Ill., etc. Philadelphia: W. B. Saunders. 1899.

A Hand-book of Obstetric Nursing, for Nurses, Students and Mothers, comprising the Course of Introduction in Obstetric Nursing given to the Pupils of the Training School for Nurses connected with the Woman's Hospital of Philadelphia. By Anna M. Fullerton, M.D., Obstetrician, Gynecologist and Surgeon to the Woman's Hospital of Philadelphia, etc. Fifth revised edition, illustrated. Philadelphia: P. Blakiston, Son & Co. 1899.

Clinical Diagnosis: The Bacteriological, Chemical and Microscopical Evidence of Diseases. By Dr. Rudolf von Jaksch, Professor of Special Pathology and Therapeutics, and Director of the Medical Clinic in the German University of Prague. Specially revised and enlarged by the author from the third English edition of the translation by James Cagney, M.A., M.D. Fourth edition. With numerous illustrations, partly in colors. London: Charles Griffin & Co., Limited. Philadelphia: J. B. Lippincott Co. 1899.

Atlas of Diseases of the Skin, including an Epitome of Pathology and Treatment. By Prof. Dr. Frantz Mracek, of Vienna. Authorized translation from the German. Edited by Henry W. Stelwagon, M.D., Ph.D., Clinical Professor of Dermatology, Jefferson Medical College, Philadelphia; Physician to the Department for Skin Diseases, Howard Hospital; Dermatologist to the Philadelphia Hospital, etc. With 63 colored plates and 39 full-page half-tone illustrations. Philadelphia: W. B. Saunders. 1899.

Original Articles.

THE TREATMENT OF THE ACUTE DIARRHEAS OF INFANCY.

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON,
Assistant Visiting Physician at the City Hospital and Assistant Physician at the Infants' Hospital, Boston; Assistant in Clinical Medicine at the Harvard Medical School.

THE acute diarrheas of infancy may be divided, on the basis of etiology, into two main classes: those of nervous origin and those due to the action of micro-organisms.

Simple Diarrhea. — The diarrheas of nervous origin are the result or manifestation of increased peristalsis. This increased peristalsis may be caused by various conditions acting through the central nervous system or by the mechanical action of undigested food. Among the most important of the conditions acting through the central nervous system are sudden changes in temperature, prolonged exposure to heat or cold, fright and fatigue. Food may fail of digestion either because it is unsuitable for digestion, or because the digestive power is functionally weak. In either case the food acts as a foreign body. The intestinal mucous membrane shows no pathological lesions, unless possibly a slight hyperemia. The number and fluidity of the dejections are increased. Except for the presence of more or less partially or entirely undigested food they are normal in character. Perhaps as good a term as any to apply to these cases of the nervous type is "simple diarrhea." They are rare in comparison with the other forms of diarrhea. Their chief danger lies in the increased susceptibility which they produce to invasion by micro-organisms. It is this danger, rather than the severity of the disease itself, which demands appropriate, early and vigorous treatment, even in the mildest cases.

Treatment of Simple Diarrhea. — The first and most important method of treatment is the removal of the cause. This is usually easy when the cause is simply fright or fatigue. When the cause is atmospheric, however, a change of climate may be necessary. When the difficulty is due to undigested food this must be removed. This is best accomplished by castor oil or calomel. As infants bear castor oil proportionately better than adults it is usually advisable to give at least two teaspoonfuls. Calomel is best given in doses of one-tenth of a grain, in combination with a grain of bicarbonate of soda, every half-hour or hour until one grain has been given. In rare instances it may also be wise to wash out the stomach and colon. The infant should be kept quiet in bed. After the cause has been removed the diarrhea usually ceases. If it does not, the treatment should then be directed to the control of the excessive peristalsis. For this purpose opium and astringents may be used. This is, with rare exceptions, however, the only condition in which the use of these remedies is allowable. Opium is best given in the form of paregoric, the dose not exceeding a few drops. I have found tannigen, in doses of from three to five grains, the best of the astringents. As the excessive peristalsis is in many instances merely the expression of general weakness, brandy, in doses of a few drops, will often be more efficacious. It is best to withhold food for a few hours and then to begin with a rather dilute, highly alkaline, pasteurized milk.

Infective Diarrhea. — Micro-organisms are the cause of the great majority of the acute diarrheas of infancy. These micro-organisms may be the usual inhabitants of the intestine or forms not normally present there. They almost invariably enter the body with the food. They are chiefly the ordinary saprophytic bacteria, among the most common of which is the hay bacillus. Bacteriological examinations of the stools in large series of cases have failed, however, to show any definite relation between any special form of bacteria and variety of diarrhea. Bacteriological examination of the discharges is present, therefore, affords no information of value as a basis for either diagnosis or treatment.

The intestines may show all grades of inflammation from simple catarrhal and simple follicular hyperplasia to follicular ulceration and the formation of false membrane. The severity of the symptoms is often no index of the degree of the pathological changes.

The constitutional symptoms are due partly to the lack of nourishment and the abstraction of fluids, but chiefly to the absorption of toxins. These toxins may be formed within the body or taken in, already formed, with the food. Among the most striking of the symptoms of toxic absorption are reflex vomiting, hyperpyrexia, prostration with cardiac depression, and nervous excitement. The most common manifestations of nervous excitement are restlessness, incessant motion and sleeplessness.

The acute diarrheas due to micro-organisms may be roughly divided into several classes which, to a certain extent, call for different lines of treatment. Certain general methods, however, are applicable to all. Among the most important of these is the prophylactic.

Prophylaxis. — This, while important at all times, is especially so in the summer, when these diseases are most common. Infants should be kept in the best possible hygienic surroundings, be given plenty of fresh air and bathed frequently. If feasible, they should be sent to the country or seashore during the summer months. Care must be taken not to overfeed them, as less food is needed in warm weather than in cool. Moreover, owing to the depression produced by the heat the child is less able to digest its food. The deficiency should be made up with water. As these diarrheas are due to micro-organisms and as these micro-organisms are almost invariably introduced with the food, it is evident that every effort should be made to give the child a fresh and sterile food. Too much care cannot be taken in obtaining, transporting and preparing milk during the summer months. It must be remembered, moreover, that the sterilization or pasteurization of milk does not destroy toxins which may be present in it; it merely prevents the formation of more. The toxins present in milk before it is sterilized may well be sufficient to cause severe or fatal symptoms.

Hygienic Treatment — While hygienic measures are of great importance in prophylaxis they are even more so in treatment. The infants should be kept quiet, given the greatest possible amount of fresh air, be lightly clothed and frequently bathed. The napkins should always be immediately disinfected in order to prevent reinfection. If the symptoms do not abate in a few days the children should, if possible, be given the benefit of a change of climate.

Dangers of Opium and Astringents. — Since, as has already been stated, the majority and the most

serious of the symptoms are due to the absorption of toxins from the intestines, it is evident that any method of treatment which prevents the natural elimination of these poisonous products in the dejections is absolutely bad. The frequent discharges are nature's attempts to cure. Hence opium in any form is positively contraindicated. It cannot do anything but harm. Astringents are unsuitable for the same reason. They are less dangerous than opium only because they are less powerful.

Classification of Infective Diarrheas. — As already stated, the infective diarrheas may be roughly divided, largely on the basis of symptomatology but partly on that of pathology, into several main groups. These are known by various names, the best of which are fermental diarrhea, cholera infantum and ileocolitis. Almost all of the summer diarrheas belong in the fermental class, ileocolitis being uncommon and cholera infantum exceptional. In making arbitrary divisions on the basis of symptomatology it must always be remembered, however, that in many cases there is absolutely no relation between the severity of the symptoms and that of the pathological lesions, and that conclusions based on the symptoms alone may be entirely erroneous.

Fermental Diarrhea.—In brief, in fermental diarrhea the number of discharges is only moderate, not usually more than ten or twelve in twenty-four hours. They vary in color from yellow and green through all shades of green. They are often watery or frothy, and may contain more or less curds and mucus, but rarely blood. The amount of the discharge is usually comparatively large. The odor is almost always offensive. In some cases it is markedly sour; in others, very foul. On this basis two main classes have been recognized, the acid fermentation and the albuminoid decomposition. It is supposed that in the first class the trouble is due to bacteria which thrive on sugars, and in the second to those which thrive on proteids. Pain and tenesmus are less prominent symptoms than in ileocolitis. The various constitutional symptoms already spoken of are present in all cases in varying combinations and degrees. All degrees of severity are seen, from the mild cases lasting a few days or weeks to those rapidly fatal in a few days or even hours. The pathological changes are comparatively slight, rarely progressing beyond the stage of simple catarrhal inflammation.

Treatment of Fermental Diarrhea. — The first indication for treatment is to remove the cause, namely, the micro-organisms and their toxic products. In mild cases a purge is often all that is necessary. Castor oil is perhaps the most satisfactory when there is no vomiting, although calomel is applicable in all cases and is altogether the best when there is vomiting. A purge is always necessary, as it is the only way in which the small intestine can be reached. In the severe cases and in all cases where vomiting is an important symptom, it is advisable to wash out the stomach. This is a simple procedure in infants, causing them but little discomfort or exhaustion. An ordinary soft-rubber catheter makes a very satisfactory stomach-tube, especially if the tip is snipped off and rounded by heat. Normal salt solution or a solution of borax or bicarbonate of soda are somewhat better than plain water. If thirst is a prominent symptom it is well to leave a few ounces of water in the stomach. In the more severe cases it is also advisable to wash out the lower bowel. This is done by passing a rather large soft-rubber catheter, with the end prepared as for washing out the stomach, high into the bowel. Several quarts of liquid from a fountain syringe, not more than three feet above the patient, should be allowed to run in and out. The same solutions may be used here as for washing out the stomach. The importance of thoroughly emptying the alimentary tract from both above and below, as well as by purging, can hardly be overestimated.

Unfortunately, it is impossible by the methods detailed above to entirely rid the alimentary tract of bacteria. Enough remain, if the conditions are favorable for their multiplication, to keep up or cause a recurrence of the trouble. The condition most favorable for their multiplication is the presence in the intestine of a suitable culture medium. This medium enters the intestine only through the mouth. Hence the next indication for treatment is to prevent the ingestion of any food which will provide such a suitable culture medium. For this reason it is best to cut off all food for at least twenty-four hours, giving only sterile water. The brilliant results claimed for barley water and rice water in the treatment of the early stages of these cases are probably due to the fact that they contain so little beside water that their use amounts practically to starvation.

Unfortunately, again, temporary starvation rarely suffices to diminish the number of bacteria to such an extent that they cannot cause trouble. The patient, however, demands and must have nourishment. The problem is to give it in the least harmful form. This is, of course, the form most unsuitable for the growth of the micro-organisms causing the trouble. The odor of the stools, as being characteristic of acid fermentation or albuminoid decomposition, would seem to offer some means of assistance. Unfortunately, this distinction is rarely possible or reliable except in the case of the very sour stools. Here an albuminoid diet, with an almost complete exclusion of sugar, is indicated and gives satisfactory clinical results. In the majority of cases, however, the process seems to be a more complex one, and there is no indication for or against any special element of the food. It must, therefore, be selected on general principles. Foods which are principally digested and absorbed high up in the alimentary tract seem, for a time, at least, most suitable. I have found albumin water, or somatose, given in ten or fifteen grain doses in water, most satisfactory.

There seems to be a very general feeling that milk in any form is unsuitable for these cases, on the ground that the pathogenic micro-organisms are usually originally introduced in milk and therefore should thrive better in it than in any other medium. The usual custom seems to be to employ some form of starchy food. I cannot see why, however, if starchy food is bad for a well baby it should be any less bad for a sick baby. I feel that the favorable results obtained from the use of these foods in these diseases are to be explained by the weakness of the foods. It is to their dilution that they owe their success. I certainly have every reason to be satisfied with the results obtained by feeding these cases with dilute milk mixtures after the initial period of starvation.

After the preliminary period of complete or partial starvation, therefore, the child should be given a mixture prepared from *fresh* milk, *low* in *all* percentages, highly alkaline and pasteurized. It is better to give

small amounts frequently than large at long intervals. Experience only can teach just what percentages are to be given in individual cases. In general, the percentage of sugar may be comparatively high, while that of the proteids must be comparatively low. The fundamental principle, however, is to give a dilute food. As the patient improves the percentages may be increased, together or singly, and the intervals of feeding lengthened until the strength and intervals suitable for a normal infant of the given age are reached.

As already stated, the first indication for treatment is to remove the cause. One way to do this is by destroying the cause. In this instance, however, the destruction of the cause involves the destruction of the patient. No germicides in doses large enough to be effectual can be used with safety. Drugs which limit to a certain extent the activity of the micro-organisms can, nevertheless, be used to advantage. After a considerable and varied experience with many drugs, including many of the newer preparations, I have discarded all but bismuth. This is best given as the subgallate. The subnitrate is almost as satisfactory. Either, to be of much use, must be given in considerable doses, not less than one or two drachms in twenty-four hours. Unfortunately, it is difficult to induce a sick infant to take this amount. About as much can be given in the form of powder, mixed with water or milk, as in any other way. It is often given suspended in chalk mixture or simple mucilage. All forms of mucilage decompose very rapidly in warm weather, and after it has been kept twenty-four hours every teaspoonful brings a large reinforcement to the enemy already present in the intestine. The subnitrate of bismuth may be safely given in suspension, however, in the following way:

℞	Ammonio-citrate of bismuth	5
	Ac. nitrici	gtt. xxx
	Aq.	ad 100

The subnitrate formed in this way will remain in suspension for several days. The objection to this preparation is the strong taste of the citric acid and the small number of grains to the teaspoon. It is possible to give this, however, when the dry powder will not be taken.

Sulphocarbolate of zinc, in doses of one-sixth to one-quarter of a grain, seem to diminish the formation of gas and to improve the odor of the stools.

Stimulation is necessary on the same indications and along the same lines as in other diseases.

Certain special symptoms, due to toxic absorption, may require special treatment in addition to that for the removal of the cause. Excessive vomiting is best treated by stomach washing, and hyperpyrexia by cold bathing or packs. Extreme restlessness usually yields to bromides but morphine may be necessary. If it is used, it is best given subcutaneously. Prostration and collapse require stimulation along the usual lines. Brandy and strychnia are most useful and must often be given under the skin.

Ileocolitis. — In ileocolitis are found the more severe pathological lesions. They are usually most marked in the colon and in the lower part of the small intestine. The discharges are numerous, usually comparatively small in amount, contain much mucus, blood and sometimes pus and membrane. The amount of fecal matter is usually small and often fairly well digested. The odor varies, being putrid when there is deep ulceration and sloughing, and almost *nil* when the discharge is composed principally of mucus. Pain and tenesmus are marked symptoms. The abdomen is often tender. Vomiting is usually not a prominent symptom.

Treatment of Ileocolitis. — The treatment of ileocolitis must be along the same lines as that of fermental diarrhea. Purgation, starvation and diet are as important in the one condition as in the other. Proteids are better borne in this condition and should make up a greater proportion of the food. Fat is not as well borne, however, and should not be given except in very low percentages. Bismuth is even more useful than in fermental diarrhea, serving the double purpose of diminishing fermentation and of mechanically coating over the inflamed surfaces.

Owing to the location of the principal lesions in the large intestine it is possible to reach the seat of disease from below. Irrigation provides a means not only for removing the micro-organisms and their toxic products, but also for cleansing the diseased surfaces and making local applications to them. Several quarts should always be used in irrigating the bowel, and the liquid should be allowed to run until it returns clear. Normal salt solution or a two to four-per cent. solution of boracic acid are most useful. Solutions of the stronger antiseptics are no more efficacious and may be dangerous. Irrigations may be used from one to three times daily. Injections of one to two drachms of the subnitrate or subgallate of bismuth in suspension in one or two ounces of freshly prepared mucilage or starch solution should be given immediately after each irrigation. In this way the bismuth is deposited directly on the inflamed surfaces. In the more chronic cases irrigations of nitrate of silver, in the proportion of 1 to 1,000, once in two or three days seem to hasten recovery. A strong salt solution should always be at hand when this is used, in case it proves too irritating.

Suppositories of a tenth or a sixth of a grain of cocaine will often relieve tenesmus. Other special symptoms should be treated as in fermental diarrhea.

Cholera Infantum. — This term should be applied only to those cases of diarrhea characterized by the most intense choleriform symptoms. It is a very rare condition. The pathological lesions are very slight, never progressing further than hyperemia and desquamative catarrh. The bacteria found usually belong to the proteus group.

Vomiting and diarrhea are constant, and both soon become almost entirely serous. As the result, all the tissues are rapidly deprived of their fluids. Thirst is marked. Wasting and prostration are extreme. The internal temperature is almost always high, although the surface temperature may be low. There is intense internal congestion. The disease is self-limited. The course is not more than two or three days, usually less. The termination is almost invariably in death, usually after marked nervous symptoms.

Treatment of Cholera Infantum. — In such a rapid and fatal disease it is evident that treatment to be of avail must be immediate and vigorous. It is probable that there is a vasomotor paralysis of the gastro-intestinal vessels. Hence food and drugs introduced into the alimentary canal cannot possibly be absorbed. They can do no good and undoubtedly may do harm.

The main indications for treatment are: (1) to empty the stomach and bowels of their toxic contents; (2) to supply fluid to the tissues which are being so seriously drained; (3) to restore the surface circulation;

(4) to reduce the temperature; (5) to keep the patient alive until the disease has run its course.

Purgatives act too slowly to be of much use in this disease, and our chief reliance must be placed in stomach washing and intestinal irrigation. They must be used early and vigorously. It is useless to expect to supply fluids by the mouth. They are almost invariably vomited. Cold, sterile water in small amounts may be tried, however. The injection of normal salt solution into the cellular tissue is the only method of introducing fluid which can be depended upon. Not less than a pint should be given in twenty-four hours. This not only supplies fluid to the tissues but assists in eliminating the toxic substances in the blood and in restoring the surface circulation.

Irrigations of cold water tend to restore the surface circulation and also to reduce the temperature. The best methods for restoring the surface circulation are rubbing, mustard baths and the warm pack. These procedures, however, are not those best fitted for the reduction of temperature. For this purpose cold, in the form of sponging, packs or baths, must be used. In the treatment of individual cases it is often necessary to determine whether it is the internal congestion or the high temperature which is doing the most harm, and then to treat the more serious condition. The relief of one, however, often aids the other also.

As food cannot be given, the patient must evidently be kept alive by stimulation. As drugs given by the mouth are not absorbed this stimulation must be given subcutaneously. The usual stimulants are to be employed. Atropine, however, seems to be the most useful. It is to be used in doses of one five-hundredth to one eight-hundredth of a grain. Morphine is indicated when the diarrhea and vomiting are extreme or when the nervous manifestations are very marked. Doses of one one-hundredth of a grain are usually sufficient. It should be given subcutaneously. Care must be taken not to give too much or to continue it too long.

In case improvement begins, stimulants and water may be given by the mouth, and soon after small amounts of a pasteurized fresh milk of very low percentages.

HYGIENICS OF THE SKIN.[1]

BY L. D. JUDD, M.D., PHILADELPHIA.

Great strides in the sciences generally have taken place within the last quarter of a century. Medicine and surgery may justly claim to lead the van, inasmuch as through the marvellous energy and skill exerted in these channels human life has been prolonged and human suffering alleviated to a marvellous degree. These fields are so vast that more than has been done, and so well done, could hardly be expected. There are great things yet to be accomplished, and it seems to me that the greatest must be developed in the line of preventive medicine within the domains of Hygeia. Drug worship seems to run rampant, and in the mad rush for the elixir of life, the medical profession, to a great degree, has ignored the simpler laws of nature. They should be devotees of Hygeia as well as students of her father, Esculapius. To teach people how to live and to avoid disease and suffering is a far nobler, though much more difficult, task than any we have in medicine — to teach how, what and when to eat and to drink; when to relax, repose and to sleep; how and when to exercise; how and when to wash and to dress, to secure the proper function of the skin. To teach these and the grand truth that if the proper advice as to these things is given and observed disease and suffering will seldom occur — is, I admit, a gigantic task. If the physician could always deal with people of brains — by that I mean people who will think reasonably and philosophically, and be willing to accept advice from those who have made a study of these things — then the task would be a pleasurable one. My attention has long been directed to the subject matter in this paper, which I will make as brief as possible, and it is given as the offspring of experience and practical knowledge.

The proper care of the skin is only secondary to that of the proper treatment of the stomach, and the ignorance and apathy in which people are resting on matters pertaining to the care of these organs, which have so much to do with health and happiness, is truly appalling.

It is the duty of our profession to instruct in these things. By hygienics of the skin I refer to the washing and the covering necessary, which embraces the treatment of the skin in health. It is not necessary to enter into an exposition on the structure and functions of the skin. Enough to say that it is nature's own covering, arranged to retain and to give off heat and moisture; to breathe in life-giving gases, and to give off noxious vapors and effete substances: that it is a breathing mechanism, and equivalent to a secondary lung. It is so planned as to be a complete protection to the economy in cold as well as in hot weather, but Eve's fall and society's demands in consequence have ordained that it shall be clothed.

That it is the most abused of all the human economy excepting that of the stomach can be readily understood and easily demonstrated. Many there are who think the frequent washing of it harmful; others that deem it essential to purge it by excessive artificial sweatings —such as in the frequent use of the Russian and the Turkish baths, the indiscriminate use of soaps, oils and fats, harsh rubbings by harsh substances, and, above all, improper material worn as underclothing — not alone improper as to material and quantity, but also as to thickness and weight. Who is there among us that has not run the gamut of all these things in his life, personally and professionally? In the first place, the proper cleansing of the skin is most essential to keep its functions in perfect working order. The first thing in the morning after rising, and, if possible, indulging in from ten to thirty minutes of deep chest breathing and light physical exercises, I advocate the warm bath of short duration, rubbing the surface of the body with the bare hands and without the use of any soap, followed immediately with the sprinkler, with cold water in force from the spigot until the skin is in a glow. Once — say every seven days — a full bath in hot or warm water, using pure Castile soap and following with the sprinkler with cold water, as on other days. When the full bath or plunge cannot be had, daily sponging with hot and then cold water is the next best. In drying the skin soft linen or crash toweling should be employed. Many claim they cannot endure the shock of the sprinkler with cold water, but after a trial, starting gradually at first if necessary, they will soon feel that a bath is incomplete without its use, and

[1] Read before the American Climatological Association, May, 1899.

that the skin seemingly craves it. It is a tonic to the heart by its action on the capillary system, as evinced in the rapid reddening of the skin. In this manner of washing perfect cleanliness is obtained, and the skin is kept in proper working order, and does not lose its elasticity. A wonderful sense of vigor is imparted, and when properly clothed the man goes to his daily duties clad in the right spirit — provided always that he abstains from overloading his stomach.

Now, what is the proper covering for the skin? There is now going on in the periodical press quite a conflict over "the underwear problem" — what and how much to wear, when to change; these are the questions sanitary science is asking. It is to be expected that the answers are as diverse as is the individuality of those answering. More are given through theory than from any practical knowledge born of proper reasoning through experience.

The ideal covering for the skin (that which is generally known as underwear) is linen — not finely woven linen, but loosely woven, as that of a mesh. We would not think of attempting to dry a wet face or body with a woollen fabric; it is too slow in absorbing moisture and equally slow in drying. We employ linen, and any close observer knows that the more loosely woven it is the quicker it dries the skin, and is much more perfect in this respect than any other fabric known; and we also know that when suspended in the air it dries more quickly. Under normal conditions our body loses through the skin from two to three pints of moisture, in the form of evaporation, in twenty-four hours. That material which rapidly takes up moisture, dries the skin and itself rapidly, is the proper covering for comfort and protection. Our skin should be kept dry as well as the air and clothing surrounding it.

The protective feature of clothing depends upon its air-holding capacity or porosity. The defect of wool in the power of quickly absorbing and eliminating moisture is a serious one, and if properly understood would do away with its use for underclothing. A woollen undergarment, when first put on the dry body, will impart to the same a feeling of warmth and comfort, which will continue as long as the evaporation of the skin is not in excess of the ability of wool to absorb and eliminate the moisture. However, if in consequence of impaired radiation of heat, as in summer time, or a greater production of heat, as by physical exercise, evaporation should be increased, wool will be no longer able to absorb the moisture as fast as excreted from the skin, nor will it be able to part with all it may absorb, hence the skin and the air surrounding it, as well as the garment itself, will be moist, and a further evaporation will be greatly interfered with.

Moisture and velocity of air augment the conduction of heat. If the wet body should under the above conditions be exposed to a draft, a rapid abstraction of heat would at once take place which would chill the body and which usually would result in a cold. It is a matter of daily observation that all those who wear wool next to the skin are very prone to contract colds.

A porous linen, having the advantage over all other fabrics of absorbing moisture and elimininating it quickly, will provide for a dry climate around our body, hence will enable us to stand extremes of heat and extremes of cold with comparative comfort. Having further the property of cleanliness and being non-irritating to the skin, it would seem peculiar that its advantage for the purpose of underclothing should not have been recognized until recently.

The fibres of wool as seen under the microscope are barbed and irregular, while those of linen are smooth and round. The advantages of linen over wool in eczemas and all skin diseases prove its protective and non-irritating qualities. J. C. Milton, senior surgeon to Dr. Johns Hospital, London, for the Diseases of the Skin, says in his paper on the "Hygienic Excellence of Linen": "For years I have been fighting the battle of linen against every kind of prejudice and opposition. Long before then I had begun to be very skeptical as to the power of woollen material to protect the wearer against the agencies which bring on catarrh, pleurisy, congestion of the lungs, bronchitis, and rheumatism, principally from observing that precisely the persons who most persisted in oppressing their frames with this kind of clothing suffered most from these ailments. I had to learn that faith in woollen is a piece of fetish worship; that while flannel is not in any way more protective than linen, if, indeed, equal to the latter, the use of it constantly brings on illness and miseries from which those who wear linen enjoy complete immunity." I would not have it understood that I am opposed to wool for clothing. It is the proper material for outer garments and top wear, as it is more impervious to the moisture of the atmosphere, and as an outside garment protects from the radical changes of this trying climate.

The day of the fad for woollen underwear, which has been rampant for over a generation, is rapidly passing, and with it will go much suffering from la grippe, pneumonia, pleurisy, and congestion of the internal organs generally. Many of us can remember the homespun linen we wore in our youth, for in the early days it was the prevailing underwear, and the colds and la grippe, which seem to be products of modern civilization, were almost unknown.

In the literature of all times in the past may be found evidences of linen as the skin covering. The art of weaving fine as well as porous linen was well known in Egypt, India and Greece. Moses, the greatest of all ancient law-givers and physicians, evidently recognized the hygienic properties of linen as underwear, for in Ezekiel xliv: 17, 18, we read: "They shall be clothed with linen garments; and no wool shall come upon them . . . they shall not gird themselves with anything that causeth sweat."

For fully three years I have thoroughly demonstrated through my own personal experience, in my family and throughout my practice, the priceless value of what I have in this paper advocated. I trust it may be the means of directing the attention of this Society to the importance of the subject, as one well within the scope of our organization.

HERNIA FOLLOWING OPERATIONS FOR APPENDICITIS.[1]

BY FRANCIS B. HARRINGTON, M.D., BOSTON,
Visiting Surgeon to the Massachusetts General Hospital.

At the Massachusetts General Hospital, from January, 1888, to August, 1897, 503 cases of appendicitis of all varieties recovered after operation by the various surgeons. The figures here presented are from a

[1] Read at the Meeting of the American Medical Association, Chicago, June 2, 1899.

personal examination of 236 of these cases. The examinations were made with the special purpose of observing the condition of the abdominal wall following this operation. The time which had elapsed since operation varied from nine months to nine years. With the consent of the visiting surgeons of the hospital and with the assistance of Dr. E. A. Codman, an interrogatory letter was sent each one of the 503 patients who recovered. Replies were received from 375. Of this number, 236 came to the hospital for examination.

These cases date from the earliest period of operative interference in appendicitis. The method of operation varied from time to time and with the different surgeons. No attempt has been made to compare the results of the various operators, as the method of treating the abdominal walls did not vary radically.

Many of those who reported themselves as perfectly well had marked general bulging of the abdominal wall on the side operated upon. Some had protrusions of the wound, and some had hernias of which they were not aware, as they caused no trouble.

The scars resulting from the operation varied greatly in character, as all scars do. In length they varied from one and one-half to seven inches. In width they varied from the linear to the very broad, in some instances being four inches wide, showing the result of stretching. Occasionally a scar showed a keloid condition.

The scars varied in color, being pale, white, brown, red and purple. The wearing of a belt seemed to make little difference in the condition of the abdominal wall, nor do I believe that belts are of much value except for a short time after operation. The scar and the abdominal wall showed the best condition in those wounds which were tightly closed. Those wounds which were partly closed showed better results than those which were left open. All of the wounds which were not tightly closed were drained usually by wicks of gauze or by tubular drainage, the amount of drainage material varying with different cases. The incisions in the unclosed cases varied, but for the greater part were oblique either in the linea semilunaris or outside of it. In the unclosed wounds during the period mentioned, from 1888 to 1897, some of the muscular or tendinous tissues were usually transversely cut. This cutting directly across muscular fibres frequently occurred in the cases which were closed at the time of operation.

Of the 236 cases examined, 85 were tightly closed at time of operation; 88 were partly closed at time of operation; 63 were open wounds, no sutures being used.

Intermuscular Spaces.—The examination of the tissues under the scar showed in many of the cases that the edges of the incised external rectus muscle or its tendon could be felt and the fingers inserted between these edges. Sometimes the edges of the internal oblique and rectus muscles could be felt. Examined with reference to the intermuscular or intertendinous spaces which could be detected, it was found that 28 per cent. of the tightly closed wounds showed such spaces; 83 per cent. of the partly closed wounds showed such spaces, and 87 per cent. of those left open showed such spaces. These intermuscular spaces result from cutting or separation of the muscles which were not brought into apposition by sutures. If they are kept apart during the healing process by gauze or other drainage the amount of separation becomes greater and more a source of danger. These conditions are increased if the muscles are transversely cut. The degree of intermuscular separation has been indicated in the following table by the term slight, medium and large, these terms referring both to the length and to the width of the spaces.

INTERMUSCULAR SPACES.

		Slight.	Medium.	Large.	Total.
Closed incisions	85	17	2	3	22 = 26%
Partly closed incisions	88	28	20	25	73 = 83%
Open incisions	63	14	17	24	55 = 87%
Total cases examined	236				

It is interesting to note that there were 23 cases, in which the wound was left wholly or partly open, where a solid wall resulted. These cases were mostly in young, muscular subjects.

General Abdominal Bulge. When we inspect the general appearance of the abdomen we often find that the wall on the side operated upon, if compared with the opposite side, protrudes upon standing or straining. The protrusion may occupy in a general way the whole of the right side or of a considerable area in the region of the scar. This protrusion I have called the "general abdominal bulge." It has been claimed that this bulging is the result of paralysis of the muscles from section of the nerves. It has seemed to me more probable that it resulted from the cutting of the muscles and tendons and the separation and stretching of these parts.

In dissecting a scar in such an abdomen, I have found the fibres of the external oblique and the internal oblique and transversalis muscles lacking in juxtaposition by a space of one-half to two inches. It can be readily seen that this separation would increase the area of the abdominal wall upon the right side. When these muscles are reunited layer by layer as they originally existed this general bulging disappears to a large extent.

GENERAL ABDOMINAL BULGE.

Closed incision	85	6 cases = 7%
Partly closed incisions	88	40 cases = 45%
Open incisions	63	29 cases = 46%

HERNIA.

We now come to the consideration of the cases of hernia existing in the cases examined.

Punctiform Hernia.—In some of the cases little openings in the scar tissue existed, usually not larger than the point of a pencil, through which could be felt the impulse of a small portion of the abdominal contents. These have been designated "punctiform hernias." There were ten of these, all occurring in the cases which were left partly or entirely open. It did not seem probable that these cases would develop into true hernias. None of them caused pain and the patients were for the most part unaware of their existence. These openings might all be closed without difficulty and should be closed if they showed a tendency to enlarge. It is probable that some of these would close in time by the proper development of the abdominal wall, as small hernias often do in infants.

Bulging in the Scar.—Among the 236 patients examined were some cases of protrusion into the scar which might develop into true hernias, but which could not be properly classed as hernias. No constriction existed and the bulging only appeared on straining. The condition indicated a general weakness in the abdominal wall at the region of the scar.

These cases were almost always accompanied by general abdominal bulging. There were 52 cases of this "bulging in the wound." In 27 cases the bulging in the wound was very slight. Two of these slight bulgings occurred in the tightly closed and were the only examples of "bulging in the scar" in this class of cases.

The other 25 cases of bulging were of considerable size, varying in length and in width from one inch to four inches. In all of these latter cases I think the wound should be reopened and tightly closed. For the most part they gave the patient no trouble, and apparently were not increasing in area.

True Hernia. — There were 27 cases of true hernia in the 236 patients examined.

Total number examined	236
" of males	190
" of females	46
True hernias in all	27 = 11½%
" in males	21 = 11%
" in females	6 = 13+%
Wounds closed at time of operation,	85 with 3 hernias = 3½%
Wounds partly closed at time of operation	88 with 11 " = 12½%
Wounds left open at time of operation	63 with 13 " = 20%

Incisions.		Punctiform hernia.	Bulging in wound.	True hernia.	
Closed	85	0	2	3	= 6%
Partly closed	88	5	29	11	= 51%
Open	63	5	21	13	= 67%

It is to be remembered that in the closed wounds the muscles and the fascia were frequently transversely cut, and the wound closed only by a single layer of stitches which would not insure accurate approximation of the cut muscles. The scars in the cases of hernia averaged four inches in length. In these cases hernia occurred somewhat more frequently in women than in men. This I think will be found to be a general fact, due probably to inferior muscular development in women. In all cases of hernia except two the patients had worn supporters.

Wounds partly closed were followed by fewer hernias than open wounds. Weakening of the abdominal wall existed in a large per cent. of the cases which were drained. This enumeration indicates that all cases should be kept under observation. It indicates that drainage should be reduced to as small an amount as is consistent with safety and dispensed with if possible.

A large proportion of these cases of weakened abdominal wall can be cured or improved by operation. I have operated upon four cases of hernia with excellent results. The operation should consist in a removal of the scar tissue. Adhesions of the abdominal contents to the scar should be separated. The wound should be large enough to allow a thorough identification of the various layers of the muscles, tendons and fascia.

The peritoneum with the transversalis fascia should first be closed; then the internal oblique and transversalis. If these muscles have been cut across they should be reunited so as to restore the original condition as nearly as possible. The external oblique should then be restored and the wound closed.

The after-treatment of a hernia operation should be similar to that employed in any closed appendix operation.

For the "interval operation" it is universally admitted that the muscular tissues should not be cut across the fibres. The McBurney incision has been very generally employed for this purpose. Since November, 1896, Dr. C. B. Porter has made a longitudinal incision through the outer border of the rectus in the "interval operation," with excellent results. This incision is now employed by a number of surgeons.

In the acute cases McBurney recommends the cutting of the internal oblique and transversalis muscles across the fibres. This is the method usually adopted. I have found it possible, by enlarging the McBurney incision for "interval cases," to obtain sufficient opening to treat a large proportion of the acute inflammatory cases. The operation is as follows:

Make an incision in the skin four to five inches long in a line with the fibres of the external rectus muscles, at such a distance from the anterior superior spine of the ilium as is desirable. Separate the muscle and its tendon without cutting for a like distance, then insert retractors one and one-half inches broad at either end. The middle of the incision should correspond to the usual position of the base of the appendix. At this point the internal oblique and transversalis muscles run nearly parallel and horizontal. These muscles should be separated, without cutting, down to the transversalis fascia, and from the ilium to the linea semilunaris. If this does not give sufficient room the sheath of the rectus may be separated in front and behind the muscle in a line continuous with the separation of the internal oblique and transversalis muscles.

The sheath of the rectus muscle is formed by the aponeuroses of the oblique and transversalis muscles. The direction of the fibres of the sheath is horizontal, being at right angles to the line of muscular fibres of the rectus. At the semilunaris line it will be necessary to use the knife or scissors, since at this point the union of the various aponeuroses is very compact. The rectus muscle can then be drawn toward the linea alba and considerable room obtained.

Care should be taken not to cut the deep epigastric artery which at this point lies inside the rectal sheath in the posterior part of the muscle. If necessary it may be tied. Two retractors each about two inches broad should be inserted one at either end of the deep incision; the retractors which have been used for the external oblique can now be dispensed with.

To approach the appendix in cases of acute inflammation, with or without suppuration, I make it a point to enter the general abdominal cavity beyond the region of the appendicular mass. The inflammatory mass is not attacked until its extent and outline have been determined and it has been isolated by a wall of gauze. This method gives good results. Having cut through the transversalis fascia and the peritoneum in a line with the deep incision we have an opening into the abdominal cavity two inches wide and from two to four or more inches long. This is sufficient for nearly all operations upon the appendix. No portion of the tissues essential to the integrity of the abdominal wall has been cut through, except for a slight incision at the semilunar line.

The opening of the rectal sheath is frequently found to be unnecessary. When the retractors are removed the muscular layers come together and even without sutures present a firm obstruction to the protrusion of the abdominal contents. If the rectal sheath has been opened it should be closed with sutures. A suture should be used to unite the cut edges of the linea semilunaris. Other sutures should be used as far as drainage will permit. If drainage can be avoided then the separated layers of muscle should be closed carefully.

All drainage should be removed as soon as safety

will permit. When the wound has healed and the stitches have been removed, the patient should be taught to make gradual and careful use of the abdominal muscles in order to restore them to their normal tone. For a month after healing a simple supporting swathe may be used, but the prolonged use of abdominal belts or trusses seems to me undesirable.

If the patient wears a firm abdominal belt and is advised to make little use of the abdominal muscles, there is danger that the muscles may become atrophied and atonic from non-use, as the muscles of the arm or leg do when in splints. Gymnastic exercises for the development of the abdominal muscles should be carefully and persistently followed out.

These exercises seem to me of great importance. Some of the best results in cases which were drained occurred in men who were obliged to resume laborious work soon after leaving the hospital. Having practised for two to three months at home those exercises which tend to develop the abdominal muscles the patient may with safety begin the more active outdoor exercises, such as bicycling, rowing, canoeing and golfing, or if his work is laborious he may resume it. The following exercises are suggested for immediate home use, the amount and duration of effort being gradually increased:

(1) Bend the trunk forward, backward, laterally, and, lastly, circularly. At first hands on the hips; to increase work, hands at neck.

(2) Lying on back, hands at neck, lift the legs stretched (very slowly) as far as the vertical; lower them slowly.

(3) Sit on bench about one foot high, feet supported under bed or bureau, bend trunk backward 45°; hands at hips.

These exercises are desirable even in cases in which some portion of the abdominal muscles or tendons have been cut transversely. If a tendency to protrusion appears an operation to reunite the severed tissues will be desirable.

For the past sixteen months I have followed this method of operation and of after-treatment in acute cases. It rarely has been necessary to cut muscular or tendinous fibres. Immediately after the wound has healed, gradual use of the abdominal muscles has been encouraged. Abdominal belts have not been used. The results thus far have been very satisfactory, even in those cases in which the wounds have been left open for drainage.

The "enlarged" McBurney incision does not interfere with drainage. After drainage has been removed and the wound has healed, if the uncut muscles are exercised, while the granulation tissue is soft and pliable, they tend to resume their original position and strength. Thus the space made by the drainage is closed and the separated muscles come into apposition. A patient of this class was allowed eight months after operation to train and enter a boat race, with the best of results to the abdominal walls.

RÉSUMÉ.

Hernia and bulging occur frequently after operation for appendicitis, and result from the separation of muscles and other tissues in the scar. They are very common when drainage has been used.

The muscular and tendinous fibres should not be transversely cut in any appendix operation unless it is unavoidable.

As little drainage material as safety will permit should be used. When drainage is necessary the wound should be closed as far as possible with sutures and the drainage removed as early as safety will permit. If the wound can be closed immediately the tissues should be restored to their normal position by suturing each layer.

Stout belts and trusses are of little value and may even do harm.

The abdominal muscles from the earliest period possible after operation should be developed by appropriate exercises.

If hernia or marked bulging appears, operation for cure is safe and satisfactory.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

THE HISTOLOGY OF THE NERVOUS SYSTEM.[1]

RECENT investigations into the fine anatomy of the nervous system have led to certain opinions which may change our views as to the neuron theory, especially as to the point that the connection between the neurons is by contiguity and not by continuity. Apáthy, some two years ago, found in the nervous system of certain invertebrates that in the axis cylinders there were distinct fibrillæ, which had been described by Golgi some ten or twelve years before, imbedded in an interfibrillary substance. These "primitive fibrillæ" he regarded as the conducting element in the nervous system. They grew in two directions: centripetally to the ganglion cell, and peripherally to the sensory, muscular or glandular cell. The fibrillæ, however, end in none of these cells, but the conducting fibrillæ pass through the cells which enfold them. They go beyond the cells and their real termination is unknown. Apáthy distinguishes sensory and motor fibres according to the arrangement of the fibrillæ in the axis cylinder. Many of the fibrillæ coming from the periphery break up into a network of elementary fibrillæ before they reach the ganglion cell, uniting with one another, but they neither end nor begin in the ganglion cell and have no connection with its nucleus. The ganglion cell he regards as the centre of the nervous process, producing a constant current and reacting to the changes caused in this current by external influences.

Bethe[2] has confirmed Apáthy's discoveries by independent investigations on the ganglion cells of the crab and also in vertebrates and man. He holds that since the nerve fibre is not the conductor, but merely contains the conducting fibrillæ, the neuron ceases to be an anatomical and physiological unit; connecting paths between different points of the nervous system run in one and the same neuron, and the old theory of connection by continuity must replace the modern idea of connection by contiguity. In the lower animals the elementary network is probably contained in the ganglion cell, but in higher animals it is wholly outside the cell. He concludes that

[1] Mitthell. aus der zoolog. Station zu Neapel, xii, 495, 1897. Ref. in Monats. f. Psych., March, 1899.

[2] Arch. f. mikroscop. Anat., li, 382. Morpholog. Arb. v. Schwalbe, viii, 95.

the neuron is not an anatomical or physiological unit; that there is no comprehensive difference between the protoplasmic process and the axis-cylinder process, and that the relations between the nerve cells and the fibrillæ are probably purely nutritive.

Apáthy has studied only invertebrates. Bethe has studied merely the fibrillæ in the ganglion cells in vertebrates. Nissl[3] advances the theory, chiefly speculative, that there is a fibrillary network between the cells, and that the gray matter of the nervous system in vertebrates is composed chiefly of this network. Like Bethe, he considers the neuron no longer a unit, but he ascribes to the ganglion cell, which is so closely bound up with the fibrillæ, an important part in nervous functions.

These views have been vigorously attacked by Lenhosséek,[4] who admits that fibrillæ exist in the axis-cylinder process, but he claims that Bethe himself has not observed an actual anastomosis between the fibrillæ from two different neurons. Bethe,[5] however, affirms that both he and Apáthy have actually seen such anastomosis and that they have never found the free ends of the fibrillæ. Lenhosséek further concludes that the neuron doctrine is not ended, but that it is based on positive anatomical data. No one has yet proved that the data on which it is based are deceptive or artefacts. The sporadic anatomical statements which Apáthy has advanced against the neuron doctrine have all been contradicted, and Apáthy's claim that the elementary fibrillæ form a connecting network in the neuropil is not yet confirmed. Physiology can bring nothing against the neuron doctrine and pathology confirms it. As long as isolated statements about the elementary network are not confirmed by others and found true in vertebrates, the neuron doctrine must be recognized. No one is justified, according to our present knowledge, in claiming that the neuron doctrine has received its death-blow. If a passage of the fibrillæ from one neuron to another should be confirmed, the neuron doctrine can still be held with certain limitations, and we must still hold firmly to the conception that the neuron is genetically derived from the neuroblast and is a trophic-cell territory complete in itself.

MOTILITY OF THE NEURON.

The theory that the neuron has an independent ameboid movement, advanced by Lépine, Rabl-Rückhard and Duval, continues to excite interest, although opposed by such observers as Lenhosséek and Ramòn y Cajal. Duval[6] again recalls the modern theory that the connection of the neurons is by contiguity and not by continuity, and argues that their prolongations are susceptible of motion owing to the contractility of the protoplasm. From this a histological theory of sleep, by retraction of these prolongations, has been deduced by Pupin, and by this retraction is also explained the arrest of nervous function leading to acts of inhibition (hysterical anesthesia or paralysis). Pergens has confirmed ameboid movements in the olfactory and retinal cells, and Demoor has noted retraction of the prolongations of the pyramidal cells in fatigue. Duval thinks the theory confirmed by the researches of Manouélian on the olfactory bulb of fatigued mice. He advances the hypothesis of *nervi nervorum*, centrifugal fibres regulating the ameboid activity of the nervous elements and acting upon the junction of two sensory neurons according to the state of attention commanded by the brain. These centrifugal fibres have been discovered by Manouélian near the glomeruli of the bulb, and he believes that such an arrangement exists elsewhere in the nervous system.

Odier,[7] after an elaborate series of experiments, has come to the following conclusions:

The nervous cell of the spinal cord is susceptible of motion, and by powerful fixation agents it may be surprised in phases of activity or rest regulated by experiment, and it shows modifications in form, volume and internal structure. The movements are manifested in the protoplasmic prolongations. Completely relaxed in a state of rest, they perform a movement of cellulipetal retraction in a state of normal activity. Artificial excitation accentuates this retraction in direct ratio to its duration and intensity. If this excitation does not produce an electric current, the retraction of the dendrites acts as if due to a current, as the prolongations parallel to the supposed current are alone affected. The cellular body, more resistant than the prolongations, yields gradually to an excitation of a certain duration. It causes equally a retraction in the direction of the nucleus. The nucleus retains its normal form longer than the prolongations and the cell body. In the advanced stages of excitation it is the seat of a manifest turgescence, which persists even after the cell body has begun to retract, but it too retracts on prolonged excitation. The chromatin is actually consumed; it is represented in a state of rest by masses regularly distributed, but they become asymmetrical after moderate excitation. If the excitations be violent and short the chromatin attains its maximum of colorability, but if the action be prolonged the colorability rapidly diminishes. The state of fatigue and exhaustion which follows extreme excitation is accompanied by retraction of the prolongations, progressive reduction of the chromatin, retraction of the cell body, later by retraction of the nucleus, and still later by retraction of the nucleolus. The chromatic points contained in the nucleus are the most sensitive to excitation. Their number decreases rapidly in direct ratio to the activity of the cell.

ARTERITIS IN NEUROPATHOLOGY.

Coulon,[8] at the Congress of French Alienists and Neurologists, has presented an excellent review of the influence of arteritis in causing pathological changes in the nervous system. He decides that, in the great majority of cases, if arteritis be added to lesions of the nerve cells, we are not authorized in considering arteritis as the cause of the nervous disease; but, although the rôle of arteritis is limited in the pathogeny of disease, it is very important as the direct cause of certain accidents: aneurismal dilatation, arterial rupture and thrombotic obliteration. A tissue does not need, in order to perform its functions normally, all the blood brought to it by the vessels, so that a considerable diminution of the vessel's calibre is compatible with normal functions. When the organ enters into greater activity, demanding increased blood supply, it may still not need all the blood that normally

[8] Revue Neurologique, August 30, 1898.

can be brought to it, but if the calibre of the vessels be diminished the organ may be normal in repose, but in exaggerated activity it will show phenomena of intermittent claudication. If the calibre of the vessel be wholly obliterated, there will of course be complete ischemia and necrobiosis in the region supplied by the obliterated vessel. If an aneurism be produced by the arteritis the phenomena observed will be due to the presence of the enlargement or aneurismal tumor or to the rupture of the aneurism, the chief cause of cerebral hemorrhage. Finally an embolus may produce thrombotic obliteration with its consequences. The rôle of arteritis in the pathogeny of nervous disease must be ascribed almost wholly to these accidents and their consequences. The influence of arteritis in the production of sclerosis is only secondary. Sclerosis is due to processes of infection or intoxication acting upon the nerve cell or the connective-vascular system, not by affecting the vessels primarily, but by affecting the other tissues together with the vessels, both arteritis and sclerosis being manifestations of the same infection or intoxication. The degree of hereditary or acquired cellular degeneration may account for the predominance of the lesions in the arterial system or the nervous elements. Intoxications generally have little action upon the arteries as the initial point of attack, but they probably have a greater influence upon existing arterial lesions. Their action, however, is uniform upon all parts of the arterial system, so that we must beware of ascribing to intoxication other arterial lesions of a circumscribed nature. In most cases the arterial lesions of the nervous system are lesions of endarteritis having the character of a local process. Their involvement of the neighboring nervous elements is to be explained only by propagation of inflammation if the arterial lesions be primary; but in most cases the arterial and nervous lesions are concomitant, rising from the same pathogenic influence, most commonly infection. This fact explains why a pathogenic cause, affecting all the elements of an organ, may determine by very variable localizations of the infection, local lesions in which we find vascular alterations by the side of alterations in the nerve cells, while the neighboring regions may be nearly or wholly exempt. The violent attacks which cause rapid necrosis of the elements determine in nervous tissue all the characters of acute inflammation. In most infectious diseases which attack the nervous system the arteritis is concomitant with the nervous lesion but does not create it. In slower inflammations the two lesions may march side by side, with greater predominance in the arterial or the nervous system, but still being independent. In diseases of a more or less systemic character the trouble is not due to arteritis. The degenerative lesions of white columns of fibres are due to lesions of their cell centres; but in the affected regions the arteries sharing in the inflammatory process naturally affect in the distribution of their lesions a topographical disposition like that of the affected region. In chronic inflammation of nervous centres ending in sclerosis, which is never of uniform extent in the organ but affects certain territories in particular, often to the exclusion of others, the sclerosis is the consequence of inflammatory processes, often repeated, determining at the same time reactions on the part of the vessels and on the part of the nervous elements in these territories; but the sclerosis is not due to the arterial lesions. In the pathology of the nervous system the rôle of arteritis is almost wholly included in that of the secondary lesions to which it may give rise: aneurismal dilatations and the local phenomena which they determine; diminutions of calibre due to thickening of the arterial walls, which may cause intermittent claudication and ischemia; embolic or thrombotic obliterations which cause foci of softening; and finally ruptures of arteries with their attendant accidents. Aside from these accidents arterial lesions, even though far advanced, may be attended with no symptoms.

PLANTAR REFLEX.

Collier[*] has studied the plantar reflex in one hundred normal adults, one hundred normal children and three hundred cases of nervous disease and his investigation confirms the opinions of Babinski, Von Gehuchten and Brissaud. In normal adults, after gentle stimulation of the sole of the foot with the finger nail or a soft quill, the following order of contraction of the muscles was observed: (1) contraction of the tensor fasciæ femoris, sartorius and adductors, and flexion of the hip; (2) flexion of the four outer toes (sometimes 1 and 2 are simultaneous, and rarely the order is reversed); (3) dorsiflexion of the ankle; (4) flexion and adduction of all the toes; inversion of the foot by the tibialis posticus; flexion of the knee; (5) contraction of calf muscles; (6) contraction of quadriceps. This normal form of the reflex characterized by flexion of the toes and marked early action of the tensor fasciæ femoris he calls the "flexor response." In infants, however, the earliest response, in the normal reflex, is in the great toe, which is drawn back; this is followed by extension and spreading out of all the toes, with eversion of the foot, dorsiflexion of the ankle, and subsequently, flexion of the hip and knee. This form, "infantile response," is also seen in the monkey. In lesions of the pyramidal tract the response is similar to the "infantile," but it is more deliberate; extension of the great toe precedes all other movements, followed by extension of the other toes and dorsiflexion and inversion of the ankle; the tensor fasciæ femoris does not contract early; the tibialis posticus and anticus and the peroneus longus contract strongly, increasing the plantar arch and fixing the ankle, which moves much less than with the normal reflex. This he calls the "extensor response." With slight lesions of the pyramidal tract combinations of flexor and extensor responses may occur. The plantar reflex is probably never absent in healthy subjects. In infants the "infantile response" persists until the establishment of complete volitional control of the legs between the second and third year of life. In sleep the reflex is diminished, but the form is preserved, except that in some children up to the age of twelve the "infantile response" returns during deep sleep. In almost all cases of lesion of the pyramidal tract the "extensor response" above described is noted. This change in the reflex is one of the first signs to appear and is the last to disappear when the lesion is temporary. It may be the only unequivocal objective sign of a lesion of the pyramidal system. It is never found under other conditions, except in the increased reflex excitability of the cord due to tetanus or large doses of strychnine, one-sixth to one-third of a grain, and is a

[*] Brain, xxii, 71, No. 85, Spring, 1899.

sign of great clinical value. In cases of total transverse lesion of the cord the "extensor response" is the only reflex phenomenon present in the lower limbs. In functional cases the reflex is hard to elicit and there is often no response in the foot, but the hip muscles usually respond; the form is the "flexor response." In tabes the reflex was absent in one-fifth of the cases; the form is the "flexor response," but it is often confined to the hip muscles. In peripheral neuritis the reflex when present is the "flexor response," which may be confined to the hip muscles. In cerebral and cerebellar tumors the "flexor response" occurs, if the pyramidal tract be not involved. In neurasthenia, chorea, paralysis agitans, poliomyelitis, myopathy and sciatica the "flexor response" is found. Pes cavus is often found in lesions of the pyramidal tract. It is intimately associated with the "extensor response" and is produced by a state of reflex hypertonicity preponderating in these muscles which respond most vigorously in the plantar reflex. In all such cases of pes cavus evidence of increased tone in certain muscles can be demonstrated. The theory that the pes cavus of spastic conditions is due to weakness of the interossei is not justified.

SPONDYLITIS DEFORMANS.

Under the name of *spondylose rhizomélique*, Marie [10] has described an affection characterized by the coincidence of a complete anchylosis of the spine with a more or less pronounced anchylosis of the proximal (root) articulations of the limbs, the small distal articulations remaining intact. The hip-joint is most affected, the arms preserving fair movement. The spine is anchylosed so that the upper part is bent forwards, and the face looks forwards and downwards. The thighs are flexed on the trunk, so that the patient is obliged to flex the knees to preserve his equilibrium. The thorax is flattened and the ribs are motionless. There is considerable pain, chiefly in the sacral but later in the cervical region, but there are no indications of acute inflammation. Marie and Levi [11] later report an autopsy on one of these cases. There was no marked ossification of the intervertebral discs, but the yellow ligaments were ossified almost completely throughout their whole length; the articular processes were united by bony anchylosis; the spinous processes were enlarged and showed a tendency to union, and the ribs were united to the vertebral bodies and the transverse processes. Radiographs of other cases show similar conditions. The prognosis is extremely grave, the disease making continual progress in spite of the most careful treatment.

The condition described by Marie had already been noted by Strümpell in the first edition of his text-book in 1884, and other cases had been reported by him [12] and Bechterew.[13] Strümpell's cases had comparatively little pain, the spine was straight and the smaller joints were not involved, unlike arthritis deformans. Bechterew had also noted slight paresis, diminished sensibility and various paresthesiæ. Bechterew, in subsequent communications, [14] points out that his cases by the presence of kyphosis, pain, sensory disturbances and certain root symptoms hinting at involvement of the cord, and by the absence of anchylosis of the hip, differ from those reported by Strümpell, Marie and others, and that in his cases heredity, trauma and syphilis seem more important etiological factors than rheumatism. He reports various cases showing symptoms of the two types of affections, which he calls "rigidity of the spine with kyphosis," and "anchylosis of the spine and extremities," the latter corresponding to the type described by Strümpell and Marie. In an autopsy of a case of the first type he found anchylosis of the spine and marked degeneration in the nerve roots and spinal ganglion, with a chronic spinal meningitis. The anchylosis did not involve the articulations of the spine, but the intervertebral discs had atrophied and the anterior portion of the bodies had become anchylosed. Bechterew regards these vertebral changes as secondary to the changes in the nerve roots and meninges and analogous to the vertebral changes seen in syringomyelia.

TORTICOLLIS.

Redard,[15] in a recent monograph, has studied the various forms of torticollis. Congenital torticollis is comparatively common and follows bad positions of the fetus, perhaps kept up by amniotic adhesions, the head being kept in such a position that the two ends of the sternomastoid are approximated for a long time. The frequency of congenital torticollis on the right side coinciding with the positions most commonly observed, its association with difficult labor, breech presentations, etc., and the coexistence of craniofacial hemiatrophy and other deformities, favor this view. Beside the forms of acquired torticollis due to cicatrices, muscular or articular troubles, etc., there is a true nervous torticollis. Lesions of the nervous centres (tumor, hemorrhage, softening), may give rise to it, or it may develop, on the side opposite the lesion, after compression of the brachial plexus or other peripheral lesions. Spasmodic torticollis must be considered as a spasmodic affection of several muscles rather than of one muscle or the muscles supplied by one nerve; it is independent of any anatomical lesion, and the etiology is still obscure, but, in most cases there are indications of neurotic heredity, degeneration, migraine, neurasthenia, etc. The spasm may be produced by various causes and is sometimes associated with general diseases. It is probably of cerebral origin; but although Brissaud holds that it is wholly psychical, a localized inhibition of the will, and that a mere touch may check it, Redard considers that it is not yet proven that spasmodic torticollis is purely psychical, since other spasms of an organic origin may at times be checked by equally slight influences. Torticollis with quick clonic spasms is usually a manifestation of some variety of tic or of paramyoclonus; true spasmodic torticollis may sometimes be a symptom of hysteria. Paralytic torticollis may exist, but it is extremely rare. Redard considers that gymnastic exercise plays an important part in all methods of treatment, but he gives a fairly complete account of the various forms of surgical intervention, Kocher having reported seven recoveries out of 12 cases where he cut all the muscles affected, and Isidor having collected 35 cases of resection of the spinal accessory, with six cures and 14 improvements.

Feindel [16] endorses the gymnastic treatment of spas-

[16] Nouvelle Iconographie de la Salpêtrière, November 1897.

modic torticollis, subscribing to Brissaud's theory of its psychical origin. His treatment consists of simple exercises, gradually becoming more complicated, and consisting of exercises of immobility and exercises of movement. In the exercises of immobility the patient at first sits with the chin supported on a rest and keeps the head motionless as long as possible, resting at the first sign of fatigue; later the patient sits without the support, leaning back in the chair, later still he stands and walks, always keeping the head motionless until he begins to feel fatigue. The exercises of movement consist of turning the head to the right or left, bending it toward each shoulder, etc., in different positions of the body. The movements are made slowly, gently and without any brusqueness, ceasing at the first onset of fatigue. Gradually, more complex movements are introduced. The sessions are at first of short duration, two to four minutes, but later they may be increased to ten minutes. They should be repeated five or six times a day, and at least once a day under the direction of the physician. With marked improvement the patient may prolong the session and be left for a time to himself. Mild galvanism for two to five minutes, or light massage, may advantageously follow one of the daily sessions of gymnastics, or they may alternate on successive days. In cases where the patients have been docile and persevering this method has led to complete cure.

TUMORS OF THE CORPUS CALLOSUM.

Devic and Pariot[17] have studied the symptoms in 18 cases of tumor of the corpus callosum and have concluded that in some cases a correct diagnosis of the seat of the tumor can be made. In every case but one the growth was a glioma, and as a rule adjacent regions are involved. The symptoms therefore vary in accordance with the variation in the neighboring parts involved. In some cases, owing either to the small size of the tumor or to the fact that neighboring parts are involved so as to give more striking localizing symptoms, a diagnosis is impossible. Devic and Pariot, however, maintain that there are two cardinal symptoms which should lead us to diagnosticate a tumor in the corpus callosum. The first is the early appearance of mental disturbances and disorders of intelligence; the second is the onset of paresis, contracture or convulsions, predominating on one side but involving the other to a lesser degree. These symptoms the authors, after a study of the cases of absence of the corpus callosum, attribute less to the lesion of the corpus callosum itself than to the involvement of the fronto-occipital association fibres or the coronal fibres from the frontal convolutions.

MENTAL DISTURBANCES IN CEREBRAL TUMORS.

Gianvilli,[18] from a study of ten cases of cerebral tumor and a careful review of the literature, concludes that when hallucinations exist in cases of tumor, they indicate an irritation of the corresponding cortical sensory centre, although we cannot affirm positively that the new growth is in the immediate neighborhood of the centre. The more the mental symptoms (torpor, intellectual arrest, failure of memory) manifest themselves in the beginning of the trouble, the more probable it is that the tumor is in the frontal lobe, and especially in the prefrontal region. In tumors in other parts of the brain the mental troubles are of later development, although they do not differ in kind from those observed in tumors of the frontal lobe. The loss of mnemonic verbal images, auditory or visual, produces a special form of dementia (graver in loss of auditory images) and indicates a definite localization in the left temporal or left parieto-occipital region. These mental troubles indicate a more or less intense and more or less diffuse alteration of the cortical morphological elements. Tumors of the corpus callosum are always (?) accompanied by mental disturbances. The modifications of sentiment which may appear in the course of a cerebral tumor have no localizing value. When the new growth presents the picture of paralytic dementia the growth is most probably in the frontal lobe. When ideas of grandeur exist the growth is most probably in the frontal lobe. A tendency to childishness or marked alterations of character indicate that the tumor is in the frontal lobe, and, by preference, in the right frontal. When, in a case of cerebral tumor, there are disturbances of the adaptation of means to the end in motor acts of a higher order, the growth is probably in the cerebral hemispheres in the neighborhood of the psychomotor zone, and by preference in the frontal region.

SENSORY DISTURBANCES IN HYSTERIA AND EPILEPSY.

Richter[19] has made a careful study of the disturbances of cutaneous sensibility and of the special senses in 71 cases of hysteria, 49 of epilepsy, and eight of hysteria and epilepsy combined (hystero-epilepsy) and has come to the following conclusions: Concentric limitation of the visual field in hysteria and epilepsy is, as a rule, a result of subjective nervous symptoms and psychical disturbances. Attacks by increasing these symptoms cause a greater limitation of the visual field. By psychical influence on the patient while using the perimeter we may as a rule diminish the limitation and thus obtain a normal visual field. An objective contraction of the field, independent of these morbid signs, was not found in any one of the 128 cases; the visual field for colors was usually not altered in position even in hysteria. A transitory change in the order of color perception is occasionally seen in the same patient. No form of disturbance of sensibility, not even hemianesthesia, has *a priori* a differential diagnostic significance in hysteria and epilepsy. A regular onset of anesthesia after hysterical attacks was not confirmed, but sensory disturbances are apt to come on as the condition grows worse and disappear as it grows better. Sensory disturbances come on without any rule after epileptic attacks; they are rare and without significance.

AGRAPHIA.

Since the days of Trousseau a considerable number of writers have maintained that there was no separate writing centre, but that writing was performed only through the medium of Broca's speech area, and that agraphia occurred either as the result of the destruction of this area or of the complete destruction of the visual area in the angular gyrus. This theory has been vigorously maintained in recent years by Dejerine and his pupils and in this country by Collins.

Gordinier[20] has recently reported a case which com-

[17] Revue de Médecine, December, 1897.
[18] Polyclinico, July 15, 1897.
[19] Archiv für Psychiatrie, xxxi, 574, January, 1899.
[20] American Journal of the Medical Sciences, May, 1899.

pletely overthrows this theory and establishes beyond dispute the existence of a writing centre. The patient was a woman of thirty-seven, who began to suffer from dizziness and later from severe headache and vomiting. About three months later she noticed some failure of vision and numbness in the right arm. Optic neuritis was present, and paresis of the right external rectus muscle. The right hand was slightly weaker than the left, but the fine and coarse movements of the hands were normal, and there was no sensory disturbance. The patient was able to recognize and to name accurately, with her eyes closed, any familiar object placed in her right hand. She understood perfectly what was said to her; she recognized familiar hymns; she could repeat orders from dictation, and speak voluntarily, without the slightest hesitation, and always correctly. She could read correctly, with the aid of glasses, ordinary print or handwriting, and she recognized numerals at once. She had, however, a total inability to write; although she understood written language perfectly, and although she could read to herself or aloud, she could not write voluntarily or form correctly a single letter, and she could not write from dictation or copy. She held the pen in a perfect manner and performed all the movements as if to write, but her writing consisted of nothing more than a series of united curves. Before her illness she could write perfectly. Later on there was some slowness in cerebration, but no other symptoms developed. An operation was attempted, but after a trephine opening was made her condition became so alarming that the operation had to be suspended, and on coming out of the ether her right arm was found to be paralyzed. Two days later she became unconscious and died.

At the autopsy a glioma, about two centimetres in length, was found at the foot of the second frontal convolution, being distinctly separated from the arm area by the precentral sulcus. Broca's convolution was found perfectly normal, as was its associated centrum ovale; the supramarginal and angular gyri, with their associated white matter, and the convolutions and white matter of the occipital and temporal lobes, were also normal. The brain elsewhere showed no pathological changes.

Reports of Societies.

NEW HAMPSHIRE MEDICAL SOCIETY.

THE one hundred and eighth anniversary meeting was held in the Grand Army Hall, Concord, May 25 and 26, 1899. The Association was called to order at 11 A.M., the President, DR. GEORGE H. SALTMARSH, of Lakeport, in the chair. There were one hundred and fifty present, which is a large attendance for a small State like New Hampshire. Prayer was offered by the Chaplain, REV. JOHN VANNEVAR, of Concord.

The reading of the records of the last meeting was dispensed with, the same having been published and distributed. The report of the Committee of Arrangements by its Chairman, DR. D. EDWARD SULLIVAN, of Concord, was followed by the report of the Chairman of the Executive Committee, DR. F. A. STILLINGS, of Concord.

The Maine, Massachusetts and Vermont Medical Associations were represented by delegates, who were the guests of the Society and were invited to take part in the proceedings.

The usual committees were appointed by the President, when the meeting was declared open for the reading and discussion of papers.

DR. CHANCEY ADAMS, of Concord, presented the first paper, which was a dissertation on

INSANITY IN ITS RELATION TO CRIME.

Dr. Adams, having had considerable experience in an institution for the care of the insane at Elmira, N. Y., made his paper very interesting in bringing to the attention of the Society many conclusions and deductions that had been made plain to him in his association with this class of people. He pointed out that it was not always easy to differentiate between the sane and the insane; that hereditary influence, especially in certain directions, had much to do with the development of certain forms of insanity. He showed that environment and centralization had much influence in child life to beget crime and other traits of character that might be avoided with better surroundings. Instances were given in which special degeneration seemed to be intensified when the mind tended to delusions of a religious, political or erotic character. The influence of a prison with the environments and associations of life in a cell formed a picture worthy of study by the philanthropist.

The discussion was opened by DR. FREDERICK L. HILLS, assistant in the New Hampshire Asylum for the Insane, who very graphically described our advancement in the knowledge of insanity and its causes, and gave it as his opinion that the conclusions of experts in this form of disease were now much better understood and recognized by the courts than ever before. He gave some characteristics of people who had been declared insane by the courts, yet he was not prepared to say that all such people should be cared for in an asylum instead of prisons. To the general practitioner, this paper and discussion was very interesting as showing that the judgment of experts in insanity is in a certain degree in accord with that of the public, in that certain forms of this disease require prison life rather than a temporary residence in an asylum.

DR. GEORGE I. CUTLER, of West Swanzey, gave a report on

SOME FORMS OF PARALYSIS OBSERVED IN COUNTRY PRACTICE.

This paper was a *résumé* of certain forms of nervous diseases as observed by the general practitioner, and some of the cases reported were but initiatory symptoms of those recognized in a more pronounced degree by the author of the first paper.

In the discussion of this paper, DR. PROUTY, of Keene, gave one condition that causes paralysis, which has not been explained in the text-books. He referred to a contusion of the circumflex and musculospiral nerves, caused by accidents. Since the advent of the bicycle these cases have become more numerous, as accidents are constantly occurring.

DR. H. L. STICKNEY, of Newport, reported a case of

SEVERE INJURY TO THE HAND,

in which he achieved much success in a conservative treatment instead of destruction of tissue; in other words, asepsis, antisepsis and cleanliness combined with

skin grafting and hypnotism to allay nervous irritability succeeded in giving the man a useful arm and hand, that under ordinary circumstances would have been sacrificed by amputation. The possibility of grafting the entire finger with equal success was suggested by Dr. Stickney.

Dr. Emdon Fritz, of Manchester, in a report on

TYMPANO-MASTOIDITIS,

described the causes and symptoms of this form of disease. In detailing the usual symptoms to be found in such cases, he said that temperature was an uncertain symptom and could not always be relied upon. He gave the common forms and varieties of this formidable disease, described the operations necessary for relief of the trouble, and described also many of the disagreeable sequences which result when the disease is left to itself or improperly treated.

Dr. O. B. Douglas, of Suncook, opened the discussion on this paper, and said that it was well that we should know that the natural course of these symptoms was an inclination to suppuration of the middle ear; and that it was necessary to understand the anatomy of these parts before commencing an operation. He described the possibility of wounding the facial nerve and its sequence — facial paralysis. He advised the use of sterilized gauze after the complete sterilization of the parts; and incidentally mentioned that in the use of the pure carbolic acid it was only necessary to use alcohol immediately afterwards to prevent the destruction of the tissue by the acid.

Dr. N. E. Guillet, of Manchester, read a paper on

VAGINAL HYSTERECTOMY, AND WHEN INDICATED.

He described the manner in which this operation was done in the French hospitals, and advised that in many instances vaginal hysterectomy instead of laparotomy should be performed.

Dr. F. A. Stillings, of Concord, in opening the discussion on this paper, said that hysterectomy is never indicated except after the microscope has shown that the patient is suffering from cancer; then after the diagnosis is fully determined, the question to be decided is what operation can we do with the most certainty of removing the entire disease. In his opinion abdominal hysterectomy was preferable to vaginal hysterectomy in cases of that kind.

Dr. J. M. Gile, of Hanover, presented a paper on

TUBERCULAR DISEASE OF THE URINARY APPARATUS.

He said the disease was not necessarily of short duration, but similar in its results to that of tubercular deposits in other parts of the body. He urged that careful diagnosis be made with the aid of the microscopist and bacteriologist. Like tubercular disease of the lungs it may prove to be rapidly fatal or run an indolent course.

Dr. H. L. Kingsford, of Hanover, described the methods of

INOCULATION OF ANIMALS AND THE RESULTS OBTAINED.

Dr. A. W. Shea, of Nashua, reported

CASES OF MULTIPLE PREGNANCY.

He gave statistics which showed that there were nine cases of multiple pregnancy out of seven hundred reported.

Dr. Edmund E. Hill, of Suncook, reported

A CASE OF PUERPURAL ECLAMPSIA WITH COMPLICATIONS.

The case was interesting in the fact that the patient had a temperature of 99° to 103° during the whole illness, being confined near the first of May and dying June 12th.

Dr. Walker, in discussing the paper, corroborated the statements of Dr. Hill, and gave it as his opinion that the eclampsia was the result of disease of the kidneys.

Dr. A. C. Heffenger, of Portsmouth, read a paper on

HEMOSTASIS IN INTRAPELVIC SURGERY,

reporting his personal experience in operations involving intrapelvic tissues, and basing his conclusions upon his observations in fifty-four cases. The key-note to success in intrapelvic surgery is absolute control of hemorrhage, and in his practice the use of properly sterilized catgut is preferred to that of silk or tendon suture. Each step of the operation was illustrated by crayon drawing.

Dr. E. F. McQuesten, of Nashua, in discussing this paper, said that death by hemorrhage can be averted, other causes cannot, therefore it is important that any one attempting the operation should thoroughly understand the anatomy of the pelvis, and should always be certain that he has control of the possibility of hemorrhage.

Dr. John D. Quakenbos, of New London, read a paper on

POST-HYPNOTIC SUGGESTION IN THE TREATMENT OF SEXUAL PERVERSIONS AND MORAL ANESTHESIA IN THE YOUNG.

He gave his personal experience in the use of hypnotism in such cases. An abstract of this would fail to do justice to the paper.

This was discussed by Dr. W. T. Smith, of Hanover, and Dr. J. H. Neal, of Rochester.

Dr. William Varick, of Concord, read a paper on

EYESIGHT OF SCHOOL-CHILDREN.

It was discussed by several medical gentlemen present and by Mr. L. J. Rundlett, superintendent of the schools of this city.

Dr. Russell Wilkins, of Concord, read a paper on

THE MEDICAL PROFESSION AND THE STATE LIBRARY.

He described the advantages to be obtained by having a large and well-appointed medical library under the care and direction of the State Librarian in this city.

The discussion of the paper was opened by Dr. Parker, of Concord, and participated in by the Librarian of the State Library and various others who were interested in this work.

During the evening of the first day, the profession in Concord united in entertaining the Society. Through the efforts of the Committee of Arrangements, J. Milnor Coit, Ph. D., of S. Paul's School, was secured to give a very interesting lecture on the properties of

LIQUID AIR,

which was illustrated by stereopticon views. A large audience enjoyed his lecture very much, at the con-

clusion of which the members of the Society and their friends were entertained by the profession in Concord for an hour or more at the New Eagle Hotel.

Other papers were read by title, referred to the Committee on Publication and will appear in the *Transactions*. The report of the Council was read and approved. The report recommended thirty new applications for membership, of which over twenty were present and signed the constitution, and the others were given until the *Transactions* are ready for press to complete their membership.

The following officers were elected: President, Charles R. Walker, M.D., Concord; Vice-President, William T. Smith, M.D., Hanover; Treasurer, M. H. Felt, M.D., Hillsborough Bridge; Secretary, Granville P. Conn, M.D., Concord. Executive Committee: Dr. F. A. Stillings, Concord; Dr. George D. Towne, Manchester; Dr. W. T. Smith, Hanover; Dr. F. E. Kittredge, Nashua; Dr. Ira J. Prouty, Keene; Dr. A. C. Heffenger, Portsmouth; Dr. G. W. McGregor, Littleton. Anniversary Chairman, Dr. M. S. Woodman, West Lebanon; Necrologist, Dr. John J. Berry, Portsmouth. Committee of Arrangements: Dr. D. Edward Sullivan, Concord; Dr. F. W. Grafton, Concord; Dr. Sibley G. Morrill, Concord; Dr. A. K. Day, Concord; Dr. George H. Parker, Concord.

A council of twenty members and a board of censors, consisting of ten members, were also elected.

At 12 o'clock the President delivered his Address, which was an able and interesting paper, in the course of which he touched upon various evils of social origin, and in graphic language showed that there was a work for philanthropists and reformers outside of temperance agitation.

At the close of the President's Address, the Society adjourned to the New Eagle Hotel, where the anniversary dinner was presided over by the Chairman, Dr. A. W. Shea, of Nashua. The Governor of the State was represented by Surgeon-General F. A. Stillings, who responded to the sentiment, "Military Surgeons of New Hampshire." The profession of law was represented by HON. J. J. DOYL, of Nashua. "The Clerical Profession" had a most eloquent response from the Chaplain, Rev. John Vannevar, of Concord, and "Women in Medicine" was happily responded to by Dr. ELLA BLAYLOCK-ATHERTON, of Nashua.

At the close of these exercises the Society adjourned to meet in Concord, May 31 and June 1, 1900.

AMERICAN MEDICAL ASSOCIATION.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN. MEETING AT COLUMBUS, O., JUNE 6, 7, 8 AND 9, 1899.

(Concluded from No. 4, p. 83.)

DR. M. ROSENWASSER, of Cleveland, Ohio, read a paper on

EARLY OVARIOTOMY; ITS PRACTICAL NECESSITY.

The motive of the author was to bring more prominently before the profession the many accidents and complications that happen with small as well as with recent growths of this kind. Neither the size nor the age of the tumor is a criterion of the possible immediate or remote dangers from its presence. In order to emphasize the special points to which attention is called, he gave a brief synopsis of a few typical cases selected to exemplify the various complications that may arise in the early stage of ovarian cystoma, or that may result from delay. His conclusions were as follows: (1) uncomplicated ovariotomy, in proper hands, is a simple operation with scarcely any risks; (2) malignancy, trauma, torsion of pedicle, infection, suppuration, adhesion to viscera, and pregnancy materially increase the difficulties and risk of the operation; (3) to avoid complications liable to occur at any time, the removal of ovarian growths should follow the diagnosis without unnecessary delay. Let the terse axiom, formulated by Dr. Howard Kelly, henceforth be the recognized rule of procedure: "From a practical standpoint all ovarian tumors must be considered as malignant until removed and proved otherwise."

In discussion, DR. C. P. NOBLE, of Philadelphia, thinks that all tumors should be removed. He had operated on four cases of tumors with twisted pedicles during the past winter. The danger of suppuration occurring makes immediate operation important and often imperative. The consensus of opinion in the discussion was entirely in favor of early operation in all instances of advanced neoplasms.

DR. ELIZA H. ROOT, in a paper entitled

STUDY AND TEACHING OF OBSTETRICS IN OUR MEDICAL SCHOOLS,

discussed the dangers of childbirth, and advocated more thorough teaching of obstetrics. The teacher must be enthusiastic, earnest and studious. Every case must be studied, and all points of interest elucidated for the benefit of the student. The diameters of the pelvis, the use of the pelvimeter, and abdominal palpation, as a means of diagnosis, should be thoroughly taught. Embryology, as a preparatory study, and later the mechanism of labor and the care of the puerperal woman should be taken up. Manikin drill is indispensable. Abnormal positions, and the management of these, should be gone over slowly. Finally, obstetric surgery and safe knowledge of the forceps should be instilled. All traction with forceps should be used in direction of the pelvic axis. Practical work should be done and recorded before graduation.

In discussion, the importance of thorough obstetric teaching was reiterated.

DR. W. W. GRANT, of Denver, Colo, in discussing

THE PROPHYLAXIS OF UTERINE CANCER,

said he considers that the field of preventive surgical disease is as interesting a study and imperative a duty as preventive medicine is to the general practitioner and sanitarian. This is particularly true in the study of malignant conditions. He quoted the methods of Dührssen and Kelly in treating these suspected cases. Grant says the only safe course is to repair every appreciable lesion of the cervix, without waiting and looking for evidence of either benign or malignant disease. Trachelorrhaphy is not a dangerous operation. With all of the cicatricial and diseased tissue removed, the lips well adjusted and united, the most common condition and cause of cancer of the cervix is eliminated. The desirability of medical supervision during the climacteric, and even before, must be admitted by all in order to meet certain diseased conditions promptly.

DR. A. LAPTHORN SMITH, of Montreal, Canada, read a paper on

THE PREVENTION AND TREATMENT OF CANCER OF THE UTERUS.

He believes that uterine cancer is not a hereditary disease, but that it is a contagious disease, probably due to a microbe which does not flourish in healthy tissue, but which luxuriates on tissues of low vitality, such as cicatrices, or in women whose whole vitality is below par. He knows of three cases of cancer occurring in nurses attending patients who died of cancer, and there was no trace of cancer in the family history of any of them. When the contagiousness of cancer is more fully recognized it may yet be possible to stamp it out by isolation of the patients. All lacerations of the cervix should be repaired. If cancer is detected early, while still limited to the angle of the tear or to the mucous membrane of the uterus, total extirpation will usually be followed by cure. If further advanced and the organ is firmly fixed and the disease has extended to the broad ligaments the author prefers to make a thorough curetting and to apply pure carbolic acid to the mucous membranes and then to perform Schroeder's amputation of cervix, which will prolong life.

DR. E. E. MONTGOMERY, of Philadelphia, in a paper,

DOES REMOVAL OF THE OVARIES EXERT A BENEFICIAL INFLUENCE ON THE SUBSEQUENT PROGRESS OF MALIGNANT DISEASE?

discussed the value of oöphorectomy in the treatment of malignant disease of the mammary gland, and the theory that the presence of the ovaries exerts an inhibitory influence on the development of such disease. If the patient is liable to the genesis of cancer when inhibition is partially removed, will she not be much more subject to its ravages when inhibition is entirely destroyed? This theory logically would contraindicate rather than render advisable the removal of the ovaries for malignant disease. The ovaries may exert an influence upon the circulation in the vicinity of the reproductive organs through the vasomotor system, and a careful consideration of the subject forces him to the conclusion that the apparent relief is afforded through the vasomotor system. Further experience is required to demonstrate not curability but sufficient palliation and delay in the processes of disease to compensate the patient for the discomfort of the additional operation. Such an operation will only be of service if done during reproductive activity.

In discussion, DR. FREDERICK HOLME WIGGIN said he believes that trauma plays an important part in the etiology of cancer, and that soon it will be proved to be an infectious disease. A common error is the belief that cancer will not develop until after menopause. Patients should know that the period of danger is between the ages of forty and fifty years. All menstrual irregularities should be considered as an indication for local examination. He condemns microscopic examination long before the time of operation, as the rapidity of the growth is increased.

DR. GOLDSPOHN thinks that Emmett's operation of trachelorrhaphy is not sufficient, as only the superficial tissue is removed, and that amputation of the cervix by Schroeder's method is the best.

DR. RIES thinks that it is a mistake to consider that laceration of the cervix is the causing factor in carcinoma. He agrees with Montgomery that removal of the ovaries is useless in cancer of the breast. It is folly to think of doing oöphorectomy on everything, from corns to headache.

DR. BONIFIELD thinks laceration of the cervix predisposes to cancer by prolonged congestion and irritation.

DR. MITCHELL thinks cancer rarely occurs in women who have not borne children or been the victims of abortion. He noted the rapid increase in the frequency of cancer.

DR. GILLIAM does not think the family physician is competent to determine the presence of cancer, and that each should be submitted to the expert for diagnosis. He thinks it is not laceration but the traumatism that is the etiologic factor.

DR. H. A. KELLY thinks we know nothing about the etiology of cancer. He does not think that microorganisms are responsible for the disease. What we want is a *modus vivendi* — something to do pending the settlement of the question of causation. Careful study of injuries of the cervix produced by childbirth should be made. Every case of atypical hemorrhage should be investigated. Microscopic examination of scrapings or a fragment of tissue can be done in fifteen minutes, or while the patient is under anesthesia. He has abandoned the radical operation with extirpation of the glands as being impracticable, too difficult and dangerous, and without good results. Uterine bougies should be inserted to aid in doing more thorough work. He considers the analogy between cancer of breast and the uterus is an erroneous one.

DR. MONTGOMERY believes that at present we do not know the cause of cancer. He thinks cancer of the body occurs in 10 per cent. rather than only two per cent., as usually stated in text-books of cases of cancer of uterus. By examining patients more frequently, as a rule, the general practitioner would soon gain the knowledge necessary to make early diagnosis. Intrauterine examination also should be practised in doubtful instances, the uterus dilated, the finger introduced, and cavity explored. Infection of the wound is often due to a secondary infection, and every precaution should be taken to avoid such infection.

DR. HENRY P. NEWMAN, of Chicago, read a paper on

EXTIRPATION OF THE UTERUS, ITS APPENDAGES, TUMORS, ETC., WITHOUT LIGATURES OR RETENTION CLAMPS; DEMONSTRATION OF A NEW INSTRUMENT FOR HEMOSTASIS, WITH A REPORT OF CLINICAL CASES.

The prime object of the angiotribe which he described is to produce absolute hemostasis and do away with ligatures or foreign bodies in the operative field. The medical profession has been struggling with this problem for a long time. It is apparent to all that the ligature is not ideal or even desirable, constituting, as it does, a foreign body, always in the nature of a complication in surgical wounds. The ecraseur was one of the early manifestations of an epoch to do away with the time-honored ligature. Its revival, in a modified form, is not without some merit. The clamp and cautery have held their place in surgery for a considerable period, and in spite of some advantages always claimed for the ligature in hemorrhoidal operations, it is probable that the cautery operation is still done an equal number of times by the ligature method. The retention clamp, likewise, has been a life-saving substitute

for the ligature, and has been a means of revolutionizing pelvic surgery, notwithstanding it is now giving way to better devices. The many methods of perfecting the absorbable sutures both in material used and manner of preparing only go to show that the profession is fully alive to the importance of doing away with the conventional ligature and suture. The Keith-Skene electric heat and Doyen crusher are among the latter methods that bid fair to solve a long-sought problem. It must not be understood that the leaving of foreign bodies in the wound is the only objection to the ligature, while it must be conceded that it is an all-important argument against its use. Other vital objections still remain: (1) Uncertainty as to slipping; (2) uncertainty as to asepsis; (3) shrinkage in the stump, thereby loosening the constricted vessels; (4) bunching together tissue, and thereby dragging upon and displacing neighboring structures. He recognizes that in the individual ligation of vessels some of the above objections would not apply; but this very desirable method of using the ligature is not always possible, or at times advisable. Again, the over-towering advantages of its substitutes (here particular reference is made to the Keith-Skene and Doyen methods) apparently leave little room for argument: (1) Immediate and absolute hemostasis; (2) perfect antisepsis; (3) an undisturbed stump, for example, no bunching of pedicle or dragging from neighboring structures; (4) the operative field free from foreign body; and (5) with the improved instruments recently constructed by Dr. Newman, promptness of execution and adaptability to nearly all tissues and surgical work.

Dr. Newman then gave the general outlines of the instrument and exhibited many cuts. His modification differs from the Thumin instrument in having longer blades, enabling the operator to include the entire broad ligament or large pedicle at a single application. The blades are narrower, so that less space is required in their adaptation to the part, and they can grasp shorter pedicles, or even sessile growths, with greater facility. At the end of one of the blades is a slightly projecting bite preventing the grasped tissue from extending beyond the blades, as it is apt to do in closing the Thumin instrument. A new or modified Thumin lever has been added to the instrument as a separate attachment. A combination mortise lock allows of an interchange at will of the lever, in applying the compression force, to that of the cross-bar and screw. While the cross-bar and screw will be found most desirable for general use, the lever has great power of compression and can be applied with a single motion or movement of the hand. This new or modified lever not only has the interchangeable lock in common with that of the cross-bar and screw referred to, but is simple in construction and adaptation, and allows of much wider separation of the blades during their application. The Thumin lever requires a partial closure of the blades and necessarily previous engagement of the pedicle or tissue to be clamped before adjusting the lock. This obstacle is overcome by the Newman instrument. Dr. Newman reports 16 cases successfully treated with the aid of his new instrument.

Dr. W. C. Bowers, of Decatur, Ala., in a paper on

NECESSARY ABORTION,

detailed the varied indications for the performance of necessary abortion. The reasons for premature emptying of the uterus are many, but fortunately very few of them act with any degree of frequency, and the indications are rarely absolute. Nephritis, advanced tuberculosis, aneurism, valvular lesions of the heart, chorea gravidarum and peripheral neuritis of pregnancy were among the indications mentioned. Probably the most common reason for interrupting pregnancy is hyperemesis gravidarum, which should not be allowed to proceed to extreme exhaustion. Pain beneath the sternum, and coffee-ground vomiting are other causes. To be pathologic the nausea must persist after the patient has arisen or be experienced when the patient is in the recumbent position. Several cases were reported illustrative of the subject discussed.

Dr. C. L. Bonifield, of Cincinnati, read a paper entitled

TREATMENT OF PATIENTS AFTER ABDOMINAL SECTION.

He considers spartein sulphate of decided value as an immediate stimulant to the heart, while digitalin may be used for a more lasting effect. The physiologic action of alcohol is so nearly identical with that of ether and chloroform that its utility is to be doubted when the system is saturated with one of these agents. Calomel is the most generally satisfactory purgative. He thinks the rectal tube is of little value for the relief of gaseous distention. Morphine constipates the bowels, checks elimination and almost always produces more or less nausea. In its place he uses codeine phosphate and chloral hydrate by the rectum for the relief of pain. To relieve the intolerable pain he employs the rectal injection of normal salt solution, a half-pint being given every two to six hours. A half-ounce of very hot water by the mouth may be allowed every hour after the first four. Bonifield considers that any surgeon who does a capital operation owes it to his patient, his profession and himself to see that everything possible is done to secure recovery. For this reason, only when it is absolutely unavoidable should an abdominal section be done in the country and the after-treatment left to a practitioner inexperienced in this work.

Dr. D. T. Nelson, of Chicago, described

THE NATURE, CAUSATION AND TREATMENT OF SHOCK.

Dr. Frederick Holme Wiggin, of New York, read a paper on

ACCIDENTAL WOUNDS OF THE FEMALE BLADDER.

While accidental wounds of the bladder occurring in the course of operations are to be deplored, and guarded against by every possible means, when they do occur the knowledge of their existence is of the utmost importance, for, as soon as discovered, they may be treated much in the same manner as simple incisions in any other part of the body. The fear of septic peritonitis has prevented a general application of this fact, but the labor of American gynecologists in proving the safety of closure of abdominal openings without drainage, even when infection is known to exist, has done much to establish on a firm basis immediate suture of wounds of the bladder. There is no more reason why a recent intra-abdominal wound of the bladder should not be sutured and the abdomen closed without drainage than in the case of a wound occurring in the bowel.

FOURTH DAY.

Dr. W. Tod Gilliam, of Columbus, read a paper on

WHAT SHALL WE DO WITH THE UTERINE FIBROID?

He detailed the history of the attitude of the profession towards these growths and painted a graphic word-picture of instances in which tragic consequences on one hand, and beneficial results on the other, had followed surgical intervention for these neoplasms. He believes that the unoffending fibroid should be let alone, unless it is a menace to life, health and happiness, when it should be removed. He argues for greater circumspection and more conservatism on the part of the surgeon. Let the smaller and less mischievous growths alone; they may or may not give trouble in the future; ten to one they will not, but if they should, it will be time enough to consider them when the exigency arises. It is the patient's prerogative to decide. It is a right vested in the human race to incur risk for the betterment of its condition, and women should have the same priceless privilege after a thorough understanding of the condition and the danger of an operation.

Recent Literature.

Urinary Analysis and Diagnosis. By Louis Heitzmann, M.D., New York. New York: William Wood & Company. 1899.

In this book four-fifths of the space is devoted to the study of urinary sediments in their relation to diagnosis of disease.

The author has a great deal to say in regard to the character of the various cell elements found in urine and of the importance of these cell findings for diagnosis. We do not agree with the pathologists who state that the character of the cells in a urinary sediment is of no value as an aid to the localization of an inflammatory process in a given case. On the other hand, we do not believe that this localization by specific cell findings is possible in the extent which Dr. Heitzmann claims for it.

To diagnose cystitis in a male by the finding of squamous cells with pus, or prostatitis, by neck of the bladder and prostatic cells, is proper, but to diagnose nephritis (catarrhal nephritis) by the finding of small round epithelial cells and leucocytes, independent of the presence of casts, is not. The small, round epithelial cell, to which type the renal cell belongs, may come from several parts of the urinary tract. These cells cannot therefore be called renal cells or the condition in which they are found diagnosed as an inflammation of the kidney unless they are associated in the sediment with casts or definite evidences of renal disease.

A Bacteriological Laboratory for Dublin. — A government bacteriological laboratory for Ireland is to be started in Dublin.

Philadelphia Hospital. — Dr. Henry W. Cattell has been elected pathologist to succeed Dr. John Guiteras, who recently resigned.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 3, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

THE STUDY OF TROPICAL DISEASE.

It is becoming more and more apparent that our new interests in tropical countries are forcing upon us not only questions of great political moment, but also numerous problems and responsibilities in the field of medicine. These responsibilities England has long realized in relation to her colonial possessions, with the result that admirable work is continually being done by skilled investigators toward the solution of the problems which tropical diseases offer. Within a year there has been published in London a journal devoted to the study of diseases peculiar to the tropics, and a school has been established whose function it is to fit men for the special medical duties which residence in tropical countries implies. Whatever the merits of the sword may be as a means of civilization, there certainly can be no question that the establishment of hospitals and research laboratories is a distinct mark of progress, which should by all means be encouraged. To see what has already been accomplished we have but to look at the work of the English in India toward combating the prevalent epidemics peculiar to that country. Apart from any definite results as regards etiology, the mere fact that men are in the field who are quite willing to risk their lives in their attempt to get at the fundamental causes of these devastating diseases has an immense moral effect upon the community in which they are working, and upon the world at large. The moment a problem is grappled with, it loses much of its terror. In the case of epidemic disease there can be no question that much of the distress results not so much from the inherent fatality of the disease as from the widespread fear which it engenders among people ignorant of its nature. It requires no great effort of memory to recall the panic, even among well-informed people, which the word "cholera" excited in our own highly civilized communities not many years ago. The fire is never so much to be feared as the wholly unreasoning panic which it is so likely to excite. It was our fortune to be in Berlin during the prevalence of cholera in the neighboring city of Hamburg a few years ago.

It was interesting to note that with all the subdued sense of fear which prevailed, there was an underlying feeling of security that man was, after all, master of the situation, as the event amply proved. It is this sense of relative security and freedom from the demoralization of panic that is always the precursor of progress in the study of epidemic diseases. This has long since been accomplished in regard to all indigenous diseases, from typhoid fever to cholera and small-pox. So far as our own country is concerned, yellow fever even has none of the terrors which were its inevitable accompaniment a few years ago. All this is due to the growth of knowledge. Modern scientific medicine has given us a clue which at least dissolves the mystery surrounding these affections, and opens a wide path of profitable research.

It is clearly evident, however, that with all that has been done in the past, much more remains for the future. Up to this time the United States has held a somewhat unique position in its relation to alien diseases of the character under discussion. We have not had an opportunity heretofore to study them adequately at their source. That opportunity has now come, and there is reason to suppose that it will not be neglected. Even during the continuance of the war with Spain valuable studies were made in relation to the pernicious fevers of malarial type which our soldiers contracted in Cuba. Enough was learned to whet the enthusiasm of the scientifically disposed to a more adequate and complete study of this and allied disorders. As one of the first results of this enthusiasm, we have recently seen an expedition sent from the Johns Hopkins Medical School to the Philippines for the purpose of making a study of diseases prevalent there. That others will follow there can be no question, and we may certainly look for results which sooner or later will have a distinct effect upon the health, and hence civilization, of the islands.

What has already been accomplished in Cuba, through the untiring energy of General Leonard Wood, we are all familiar with. The report comes as we write that yellow fever has practically been wiped out of Santiago, which should be a source of congratulation not only to the chief agent of this triumph, but also to the country he so ably represents. Brilliant as this success is, we need to go deeper, and probe out, if possible, the sources of the disease and all the conditions under which it originates and flourishes.

Such results can only be obtained by systematic work, extending over considerable periods of time and conducted by highly trained specialists. Were adequate arrangements made we have no question that men thoroughly qualified could be found in abundance, who would be quite willing to undergo the hardships and possible dangers which life in a tropical or semi-tropical country would involve. Here is evidently an opportunity for a true university extension movement, and it is a work which, to our mind, the universities with medical departments might, with great profit, assume. It would be quite possible to establish stations in Cuba, for example, to which might be sent accredited representatives of a university, for the purpose of working out some of the many medical problems which the tropics afford. Such a plan, which would appear not difficult of execution and not of necessity costly, would do much to hasten the time when diseases now dreaded because not understood would be in great measure preventable. To arrive at an adequate prophylaxis evidently means much painstaking study on the spot. With that possibility opened by the establishment of laboratory research stations, we are confident that yellow fever and other conditions, so inimical to health and life in those countries, would be, in due time, relegated to the growing category of preventable diseases.

AS TO CREMATION.

Popular feeling is evidently changing with regard to cremation. Statistics of the last few years show a constantly increasing number of establishments, for the most part connected with cemeteries, where the process of incineration may be carried out. This has been due to an improved public opinion and to the partial lapse of the superstitious point of view to which civilized peoples in this matter have so long been slaves. The strong impulse given to burial by the church has gradually given way to a more liberal conception, which sees in the disposal, by burning, of the human remains nothing inimical to religious ideals.

In addition, however, to this deeply rooted sentiment regarding the immediate destruction of the body after death, there can be no doubt that there is a strong personal feeling that finds comfort in burial, and imagines, at least, it will experience added pain in the rapid destruction of the body. This is no doubt a mere sentiment, engendered and fostered by centuries of custom. That it will finally give way entirely to more rational feelings appears likely. If we permit ourselves a moment to think of the conditions after death of the buried body, we are forced to recognize the unesthetic side of the whole matter, quite apart from considerations of hygiene and public health.

An interesting, if unpleasant, paper was published recently in *Public Health* and quoted in the *Journal of Tropical Medicine*, which brings home to us forcibly the situation. In speaking of soil used for burial purposes, the writer says:

"The suitability or otherwise of a soil for the site of a cemetery depends on the same conditions, — namely, the presence or absence of nitrifying bacteria, its permeability to air, and its humidity and drainage — that determine its fitness or unfitness for the treatment of sewage. In the one class of soils bodies undergo dessication, and the soft parts "return to dust" in the course of a few years; in the other they putrefy, and instead of decomposition and disintegration they remain for years — in fact for indefinite periods — festering masses of corruption. An official

inquiry in Germany some years ago showed that in the "loess" four years sufficed for the disappearance of everything but the bones and hair, whereas in stiff wet clays the bodies still presented stinking, putrid masses; and in excavating the churchyard of St. Andrew's, Holborn, pre-eminently a "dead" earth, there was little difference to be seen between the interments of twenty and of two hundred years previously. Yet with few exceptions the situation of the cemeteries around London makes it clear that, whatever considerations determined the choice of the localities, the nature of the soil was not taken into account."

What is true of London is, no doubt, though possibly to a less degree, true of cemeteries everywhere, established many years ago. These facts should be borne in mind, and should certainly have influence in leading to a wider adoption of cremation as a method of disposing of the dead. To the sentimentalist nothing could exceed the repulsiveness of the idea of a putrefying body remaining for years undecomposed into its primitive elements, while to the sanitarian such a possibility brings up visions most unpleasant to contemplate.

The expense of cremation at present stands somewhat in the way of its more universal adoption, but we have no doubt that with a larger demand more adequate means at smaller cost would quickly be provided. We trust the day may be not far distant.

A CLOSER RELATION BETWEEN MEDICAL PROGRESS AND THE GENERAL PRACTITIONER.

Improved methods of medical practice come very slowly into general use. When we hear addresses on recent progress in medicine, we are apt to think that every one will have the benefit of this knowledge, which has become common property by being published to the world. In reality, however, it takes a long time before the community as a whole is benefited by advances in medicine. For example, we hear much about the value and importance of the microscope in modern medicine. Clinical microscopy is held to be one of the great advances made in modern medicine, and yet outside of our large cities how few of our citizens have any benefit from progress made in this direction. The x-ray is another illustration of the failure of our community to reap the advantages of progress in medicine. Although recognized as one of the great discoveries of medicine, very few of our citizens outside of our large cities have the benefit of the x-ray when through accident or disease they might be helped by its use.

Can anything be done to more quickly bring into general use new methods of medical practice? We believe that more might be done through our medical societies and more also by our boards of health. It is of the latter only that we wish now to speak.

Our boards of health have already done a great deal in this direction. The free examination of diphtheria cultures, of sputum for tubercle bacilli, of the blood for the plasmodia malariæ is being used by practitioners in remote country districts. Those practitioners are not merely being helped in the diagnosis of these diseases but they are learning the value of the laboratory and the microscope. Their quick appreciation of these examinations shows that they are ready to employ modern methods if it is possible for them to do so, and that if the facilities for the use of other examinations were to be offered to them, these also would be employed.

All over the State of Massachusetts local boards of health are establishing their own laboratories for the making of the free examinations which we have mentioned. In at least one town, Brookline, the examinations made in the Board of Health's laboratory are not confined to those which aid in the diagnosis of contagious diseases. Chemical and microscopical examinations which aid in the diagnosis of other diseases are also made, and are already availed of. As these examinations concern the health of the individuals and not of the public, they are not and should not be free, but the cost should be borne by the individual for whom the examination is made. At the Brookline laboratory urinary analyses, blood examinations, examinations of contents of the stomach, etc., are made for a fixed fee.

In the same way in those communities where there is no x-ray apparatus to which the practitioners can have access, it is suggested that the local board of health might have an outfit for the use of the physicians, the expense here also being borne by those patients who have the benefit of it. One of the cities of Europe, to our knowledge, has an establishment with an x-ray outfit, to which any of the physicians can bring their patients.

Paternalism or socialism in medicine should be guarded against, but where a community would otherwise be without methods of medical practice which have been proved to be of great value, more might be done than is now done to secure for the community the benefit of these methods. We should not merely try to extend by research our knowledge of medicine but should also strive to secure for our citizens the benefit of such knowledge already obtained. The value of any medical discovery is proportional to the use that is made of it, and the experiment now in progress at Brookline will be watched with interest.

MEDICAL NOTES.

Professor Sanarelli to Visit America. — It is reported that Professor Sanarelli is about to visit the United States to study the effects of his serum in the treatment of yellow fever.

A Centenarian. — Mrs. Phœbe Doty Hedges, residing between the borough of New Providence and Summit, New Jersey, is reported to have celebrated her one hundred and first birthday.

A Sign of Progress. — It is reported that Dr. Dupont, of Paris, is collecting by the phonograph the different cries of the insane, paralytic, epileptic, idiotic, and of those in various deliriums.

Appointment of Professor Brissaud. — It is announced that Professor Brissaud has been appointed to the chair of history of medicine and surgery at the Paris Faculty of Medicine.

A Numerous Progeny. — It is stated that a French-Canadian woman, twenty-eight years of age, recently gave birth to her third pair of twins in three years. Both father and mother were also one of twins.

A New Neurological Society. — We learn from *Science* that a neurological society was formed in Paris on June 8th, with Professor Joffroy as President. The society will issue the *Revue Neurologique*, which will appear on the 15th of each month.

Yellow Fever at Hampton, Va. — The outbreak of yellow fever in the Soldiers' Home at Hampton, Va., which at the date of writing had resulted in forty cases and eight deaths, is reported to have been brought under control. The probability of its having originated in the neighboring village of Phebus has been established. Norfolk is at present free from invasion.

Yellow Fever at Santiago de Cuba. — A letter we have just received from Gen. Leonard Wood, M.D., from Santiago de Cuba, says: I have just returned from the United States and find that we are having a little yellow fever here. The mortality amongst officers has been exceedingly high; all who have contracted the disease up to date have died. The total mortality has been about 25 per cent. I believe that we have the epidemic under good control and that we have seen the worst of it.

Asylum for Insane Indians. — As stated in the *Medical News*, the asylum for insane Indians at Canton, S. D., for which Congress made an appropriation of $42,000, with an additional $3,000 for the purchase of ground, will soon be erected. Out of 250,000 Indians in the United States there are only 58 who are insane, one doubtful, six idiotic and two partly idiotic. It would seem, then, that the simple physiological life of the barbarian has some advantage over the brain-paralyzing existence characteristic of civilization.

A Memorial of Sir Thomas Browne. — A movement is on foot, according to the *Medical Record*, for the erection in Norwich, Eng., where he resided for a period of forty-six years, and in which city he died in 1682, of a memorial statue of Sir Thomas Browne, the author of "Religio Medici." While excavating a grave in the chancel of St. Peter's some years ago, a coffin was broken open, which proved to be that of Sir Thomas Browne, the skeleton being in good preservation, and the hair of the beard very profuse.

Christian Science Legalized. — We learn from the *Journal of the American Medical Association*, that under the new medical act, "Christian Scientist healers," are, for the first time, given a legal status in Illinois. The act contains the following clause explicitly prohibiting interference with them: "This act shall not apply to any person who ministers to or treats the sick or suffering by mental or spiritual means without drugs or material remedy." Under this act the "Christian Scientist" has full right to practise without supervision or control by any authorities.

An American Surgeon Honored. — As an illustration of the interest which European surgeons are taking in the work of their American colleagues, we learn from the *Philadelphia Medical Journal* that Professor Kocher, of the University of Berne, extended the courtesy of his clinic to Dr. W. S. Halsted, of Johns Hopkins, July 7th. Dr. Halsted performed his operation for hernia, demonstrating his method to the originator of one of the most famous operations for this class of surgical cases. The case proved to be one with a deficiency of the conjoint tendon and particularly favorable for Dr. Bloodgood's transplantation of the rectus muscle, which was done. Dr. Kocher was especially impressed with the resection of the veins of the cord and the precaution against hemorrhage, in order to prevent pressure on the vas and consequent atrophy of the testicle.

"Non-Combatants" in the Philippines. — *Freedom*, an American paper published in Manila, under date of May 1, 1899, has the following item: "Members of the hospital corps have all been supplied with Krag-Jorgensen carbines. Incidentally it is noticed that they have removed the red cross from their uniforms. It is not compatible with United States soldiering for men wearing the red cross to be armed, as with that insignia they are supposed to be non-combatants. The Filipinos, though, have refused to notice hospital-corps men as such in this war and several times have wantonly fired upon them. Hence the carbines." In another column of the same issue, in referring to the attack on Malolos, the paper says: "Dastardly and cowardly as usual, Filipino sharpshooters secreted themselves where they could shoot the Oregon wounded under the tree where Captain Brosius, assistant surgeon, was working. This bestial practice was carried on nearly all day also at the dressing station where Major Ellis and Assistan tsurgeon De Mays were engaged. Private Clark, of Company A, was brought in with a broken arm and while Hospital-attendant Bollan was lifting him from the stretcher Clark was shot through the spine and died a few moments later. Another shot cut Bollan's canteen strap. Privates Peel and West of the hospital corps were each shot through the head. Filipinos dearly love to shoot or mutilate the wounded and hospital attendants. It is according to their ideas of valor."

FIRST RESERVE HOSPITAL IN MANILA. — Recent unofficial reports from Manila, dated early in May, state that this hospital is located in the walled city, or "Old Manila." The buildings, made of stone, are large, roomy, well lighted and ventilated. The grounds have many shade trees, tropical flowers and plants, large walks and driveways. A few tent-wards prevented overcrowding and gave plenty of room to each patient. There were at the time of writing 22 wards with a total of 960 patients, a majority being wounded. Since the outbreak of the insurrection, 932 cases of gunshot injuries had been treated at this hospital. A large number of these were but slightly wounded, and these, after receiving attention and being permitted to rest for a few days, were soon returned to duty — usually at their own request. The number of wounded remaining on May 1st was 430. There had been since February 5th a total death-list of 193 from wounds received in action. The patients are given careful attention and scrupulous cleanliness is maintained. The drinking-water is all distilled, the hospital owning its condenser and ice plant. Since the insurrection 260 wounded insurgents have been treated at this hospital, receiving every attention. The hospital-corps men have worked hard and deserve great credit for the excellent results obtained. The hospital is under the command of Major W. D. Crosby, U. S. Army. The patients are cared for by a large staff of medical officers, 11 hospital stewards, 20 female nurses and 160 privates of the hospital corps.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 2, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 59, scarlet fever 34, measles 7, typhoid fever 22.

QUARTERLY MEETING OF MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH. — The quarterly meeting of this Association was held July 27th at Gallop's Island, Boston Harbor. Dr. E. G. Cutler read a paper on "The Incubation and Infective Periods of Infectious Diseases."

NEW YORK.

A FATAL CASE OF RABIES. — A case of rabies of unusual interest terminated fatally at the New York Hospital on July 28th. The patient, Capt. George Bockhaven, master of the freight steamer *Corona*, and fifty-five years of age, was a man of unusual intelligence and self-possession. He was bitten in several places by a strange dog on June 12th, and the first symptoms of rabies appeared July 26th. At the Pasteur Institute a thorough test of the Buisson hot vapor treatment was made, and when it was found that this had no effect whatever upon the disease he was removed to the New York Hospital, where, as a last resort, a certain amount of blood was abstracted and a strong saline intravenous injection made, at the suggestion of Dr. Gibier. Up to almost the last moment the patient was perfectly cool and deliberate, and described his feelings quietly and intelligently.

AN OUTBREAK OF RABIES IN ERIE COUNTY. — A widespread outbreak of rabies among dogs, horses and cows is reported in Erie County by Commissioner Weiting, of the State Agricultural Department, and four persons who have been bitten by rabid animals there are now undergoing preventive treatment at the New York Pasteur Institute. The origin of the trouble has been traced to a large St. Bernard dog which ran for nearly forty miles, biting everything that came in its way, before it was killed.

TUBERCULOUS CATTLE. — An official inspection recently made of the cattle of Ex-Gov. Levi P. Morton, near Rhinecliff, on the Hudson, one of the most valuable herds of Guernseys in the county, showed that a large percentage of the animals, nearly sixty in all, were affected with tuberculosis.

TYPHOID FEVER IN FLUSHING. — At Flushing, in the Borough of Queens, which is said to have hitherto been remarkably free from this disease, there is an outbreak of typhoid fever. Over twenty cases, seven of which are now at the Flushing Hospital, with one death, have thus far been reported. Since last April the village pumping station has not furnished sufficient water to supply the demand, and the typhoid is attributed to the impure water of one or more ponds which have been utilized to supplement the supply.

STATISTICS OF TYPHOID FEVER. — The State Board of Health has been making a study of the increased prevalence of typhoid fever during the past year, and has found that in the small towns and rural districts, in which the disease is usually more prevalent than in cities, the deaths from typhoid were in 1898 at the rate of 174 in 10,000, against 149 in 10,000 in 1897. The cities of the State, however, do not all have a lower death-rate from the disease than the rest of the State, and the Board, in the tabulation of their mortality statistics, groups them for convenience into three classes: those having a death-rate below that of the rural districts, those having about the same rate, and those having a decidedly higher rate. In the first class are placed New York, Yonkers, Utica and Auburn; in the second, Buffalo, Rochester, Syracuse and Troy; and in the third, Albany, Elmira and Binghamton. In 1898 Rochester and Yonkers alone had a decrease, but in New York and Auburn the increase was slight. The most remarkable increase was in Troy, which for that year must be placed in the third, instead of the second class.

TWO CENTENARIANS. — Catharine Vidal, unmarried, a native of New York City, died in Mount Vernon, N. Y., on July 26th, at the age of one hundred. On July 23d Alice McMahan, a spinster, said to be one hundred and five years old, who emigrated from Ireland sixty years ago, sailed for her native land on board the Cunarder *Umbria*.

Miscellany.

POISONOUS PANTRIES.

It is very desirable that the conditions under which food may become poisonous should receive more practical consideration than they do. Dr. W. W. Stainthorpe, of England, has called attention to some glaring defects in the location of food storerooms, which are worthy of attention. In house construction the position of the pantry is too often treated as of minor importance. In some houses the space under the stairs or some equally unsuitable and inadequately lighted and ventilated place is thought good enough for the purpose. In a great number the pantry is a small offshoot from the house, the ceiling, floor and walls often being damp, owing to faulty construction; in some of these matters are rendered worse by the water taps being placed therein without any provision being made for carrying away the droppings from the tap or overflow from vessels into which the water is run. Frequently the closet — ordinary or pail — is only a few feet from the pantry window. One of the most frequent entries in his inspection note-book is "defective yard pavement," permitting of soakage of filth into the soil underneath, with all its evil consequences. — *Medical Record.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 15, 1899.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.

Newburyport	14,915	8	4	37.50	—	12.50	12.50	—
Melrose	14,032	3	—	—	—	—	—	—

Deaths reported 1,835; under five years of age 822; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 532, consumption 168, acute lung diseases 72, diarrheal diseases 405, diphtheria and croup 35, typhoid fever 34, whooping-cough 21, cerebro-spinal meningitis 19, scarlet fever 12, measles 4, erysipelas 2.

From whooping-cough Philadelphia 9, Pittsburg 4, Boston and Lowell 2 each, Nashville, Charleston, Lawrence and Chelsea 1 each. From cerebro-spinal meningitis Baltimore 3, Philadelphia, Boston, Washington and Somerville 2 each, Worcester, Lynn, Springfield, Chelsea, Fitchburg, Taunton, Newburyport and Amesbury 1 each. From scarlet fever Washington 3, Philadelphia, Pittsburg and Lowell 2 each, Baltimore, Cincinnati and Lynn 1 each. From measles Boston and Pittsburg 2 each. From erysipelas Baltimore and Washington 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 11,404,408, for the week ending July 1st, the death-rate was 15.7. Deaths reported 3,427; acute diseases of the respiratory organs (London) 159, measles 110, diarrhœa 80, whooping-cough 79, diphtheria 71, scarlet fever 35, fever 28, small-pox (Hull) 5.

The death-rates ranged from 10.4 in Blackburn to 22.5 in Gateshead; Birmingham 15.4, Bradford 14.8, Cardiff 13 5, Hull 17.4, Leeds 14.4, Liverpool 21.5, London 14.9, Manchester 21.3, Newcastle-on-Tyne 14.5, Nottingham 12.9, Portsmouth 15.0, Salford 17.9, Sheffield 20.6, Swansea 13.1, West Ham 11.8.

In the thirty-three greater towns of England and Wales with an estimated population of 11,404,408, for the week ending July 8th, the death-rate was 16.0. Deaths reported 3,496; acute diseases of the respiratory organs (London) 194, measles 133, diarrhœa 98, whooping-cough 85, diphtheria 81, scarlet fever 35, fever 24, small-pox (London) 6.

The death-rates ranged from 10.6 in Croydon to 24.8 in Mancher; Birmingham 12.9, Bradford 12.1, Cardiff 15.2, Gateshead 15.7, Huddersfield 17.6, Leeds 15.1, Liverpool 24.2, London 15.0, Newcastle-on-Tyne 16.6, Nottingham 17.0, Portsmouth 11.8, Sheffield 21.5, Swansea 12.1.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 22, 1899.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Whooping-cough.	Diphtheria and croup.

Newburyport	14,915	7	4	14.28	14.28	—	—	—
Melrose	14,032	2	—	—	—	—	—	—

Deaths reported 2,918: under five years of age 1,538; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 1,068, consumption 261, acute lung dis-

eases 152, diarrhœal diseases 894, diphtheria and croup 60, whooping-cough 37, typhoid fever 24, cerebro-spinal meningitis 18, measles 17, scarlet fever 12.

From typhoid fever New York 8, Pittsburg 4, Boston 3 Baltimore and Washington 2 each, Providence, Springfield, Holyoke, Salem and Everett 1 each. From cerebro-spinal meningitis New York 8, Baltimore and Washington 2 each, Boston, Worcester, Gloucester, North Adams, Newburyport and Hyde Park 1 each. From measles New York 13, Pittsburg, Providence, Fall River and Somerville 1 each. From scarlet fever New York 10, Boston and Fitchburg 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,406, for the week ending July 15th, the death-rate was 16.9. Deaths reported 3,690; acute diseases of the respiratory organs (London) 177, diarrhœa 204, measles 124, diphtheria 91, whooping-cough 76, scarlet fever 32, fever 24, small-pox (London and Hull 1 each) 2.

The death-rates ranged from 11.0 in Croydon to 24.6 in Salford; Birmingham 18.6, Bradford 15.9, Cardiff 11 8, Gateshead 17.6, Hull 12.9, Leeds 17.1, Liverpool 23.3, London 15.9, Manchester 21 5, Newcastle-on-Tyne 19.2, Nottingham 19 4, Portsmouth 12.0, Sheffield 24.1, Sunderland 16.1, Swansea 20.1, West Ham 12.0.

METEOROLOGICAL RECORD

For the week ending July 15th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 29, 1899.

L. W. ATLEE, surgeon, detached from the "Bennington" and ordered home via "Solace."

G. ROTHGANGER, passed assistant surgeon, detached from the "Marietta" and ordered home and to await orders.

M. K. JOHNSON, passed assistant surgeon, detached from the Naval Hospital, New York, and ordered to the "Marietta."

W. M. WHEELER, assistant surgeon, when discharged from further treatment at hospital, Yokohama, Japan, ordered home in the "United States" and to await orders.

T. M. LIPPITT, assistant surgeon, detached from the "Solace" and ordered to the "Baltimore."

L. W. PLUMMER, assistant surgeon, ordered to the Naval Hospital, New York.

J. W. ROSS, surgeon, retired, granted leave for one year abroad.

H. A. DUNN, assistant surgeon, detached from the "Panther" and ordered to the Washington Navy Yard.

L. L. VON WEDEKIND, passed assistant surgeon, detached from the hospital, Cavite, P. I., and ordered to Mare Island, Cal.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 27, 1899.

MEAD, F. W., surgeon. To proceed to New York, N. Y., and assume temporary charge of the Purveying Depot. July 21, 1899.

GEDDINGS, H. D., passed assistant surgeon. Relieved temporarily from duty on the commission for the scientific investigation of yellow fever, and assigned to temporary duty in the Hygienic Laboratory. July 22, 1899. To proceed to Boston, Mass., for special temporary duty. July 25, 1899.

PERRY, J. C., passed assistant surgeon. Detailed for duty in the office of the U. S. Consul at Hong Kong, China. July 22, 1899.

GARDNER, C. H., passed assistant surgeon. To assume temporary charge of the Port Townsend Quarantine. July 24, 1899.

SPRAGUE, E. K., passed assistant surgeon. Granted leave of absence for twenty-seven days from August 7, 1899. July 27, 1899.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for thirty days from August 6, 1899. July 27, 1899.

TABB, S. R., assistant surgeon. Upon being relieved from duty at Baltimore, Md., to proceed to Savannah, Ga., and assume command of the service. July 22, 1899.

FOSTER, M. H., assistant surgeon. Upon being relieved from duty at Savannah, Ga., to proceed to the Port Townsend Quarantine Station, and report to the commanding officer for duty. July 22, 1899.

LUMSDEN, L. L., assistant surgeon. To proceed to Port Townsend, Wash., and assume temporary charge of the service. July 24, 1899.

BILLINGS, W. C., assistant surgeon. Relieved from duty at the Immigration Depot and directed to report to the commanding officer at New York, N. Y., for duty and assignment to quarters. July 26, 1899.

FOX, CARROLL, assistant surgeon. To report to commanding officer, Baltimore, Md., for duty and assignment to quarters. July 26, 1899.

MCCLINTIC, T. B., assistant surgeon. To report to commanding officer Cape Charles Quarantine, for duty and assignment to quarters. July 26, 1899.

CURRIE, D. H., assistant surgeon. To report to commanding officer at Louisville, Ky., for duty and assignment to quarters. July 26, 1899.

GOLDBERGER, JOSEPH, assistant surgeon. To report to Surgeon L. L. Williams, Immigration Depot, New York, N. Y., for duty. July 26, 1899.

KORN, WM. A., assistant surgeon. To report to commanding officer, Chicago, Ill., for duty and assignment to quarters. July 26, 1899.

HOLT, J. M., assistant surgeon. To report to commanding officer, St. Louis, Mo., for duty and assignment to quarters. July 26, 1899.

TROTTER, F. E., assistant surgeon. To report to Surgeon L. L. Williams, Immigration Depot, New York, N. Y., for duty. July 26, 1899.

VOGEL, C. W., assistant surgeon. To report to commanding officer, Boston, Mass., for temporary duty and assignment to quarters. July 26, 1899.

TUTTLE, JAY, acting assistant surgeon. Granted leave of absence for seven days. July 22, 1899.

PROMOTIONS.

HENRY GAHN, hospital steward. To be hospital steward and chemist. July 17, 1899.

W. L. STEARNS, hospital steward. To be hospital steward and assistant chemist. July 17, 1899.

APPOINTMENTS.

CARROLL FOX, of Pennsylvania, commissioned as assistant surgeon. July 25, 1899.

THOMAS B. MCCLINTIC, of New York, commissioned as assistant surgeon. July 25, 1899.

DONALD H. CURRIE, of Missouri, commissioned as assistant surgeon. July 25, 1899.

JOSEPH GOLDBERGER, of Pennsylvania, commissioned as assistant surgeon. July 25, 1899.

WILLIAM A. KORN, of New Jersey, commissioned as assistant surgeon. July 25, 1899.

JOHN M. HOLT, of New York, commissioned as assistant surgeon. July 25, 1899.

FREDERICK E. TROTTER, of New York, commissioned as assistant surgeon. July 25, 1899.

CHARLES W. VOGEL, of Maryland, commissioned as assistant surgeon. July 25, 1899.

APPOINTMENT.

DR. HENRY F. HEWES has been appointed physician to outpatients at the Massachusetts General Hospital.

THE PROTEIDS OF THE URINE.[1]

BY WILLIAM B. HILLS, M.D., CAMBRIDGE, MASS.,
Associate Professor of Chemistry, Harvard Medical School.

The following cases are reported particularly for the purpose of calling attention to the form of proteid contained in the urine:

Case I. Clinical history unknown. The urine was first submitted to me February 13, 1897, to be analyzed for arsenic. I have since made eight examinations of the urine. The daily quantity, so far as I have had the opportunity of observing it, has been 1,750–2,300 cubic centimetres. Urea, 22.5–26.9 grammes. Both the heat and nitric-acid tests have showed the constant presence of a coagulable proteid. The quantity of proteid has not varied appreciably; by estimate usually about one-eighth per cent. On one occasion a quantitative determination showed 1.4 grammes per litre.

When the urine, faintly alkaline with ammonium hydroxide, was saturated with magnesium sulphate, or half-saturated with ammonium sulphate, a precipitate was obtained. These precipitates were thrown upon a filter paper, washed with a saturated solution of magnesium sulphate, and a half-saturated solution of ammonium sulphate respectively, and dissolved in distilled water (the adherent salt rendering the precipitate soluble). The solutions thus obtained contained a proteid coagulable by both heat and nitric acid, that is, globulin. The filtrates from the precipitates produced by magnesium and ammonium sulphates contained no detectable trace of albumin.

These results have been constantly obtained in the examination of the urine in this case, which is apparently a chronic nephritis, either the interstitial type or amyloid infiltration, and of special interest as being a case of pure globulinuria. Such cases have seldom been reported.

Case II. Scarlet fever in a boy of eighteen years. The urine examined on the tenth day was normal as to specific gravity and normal solids, contained a minute trace of albumin and, in the sediment, a few red blood corpuscles, leucocytes, and epithelial cells, apparently from the neck of the bladder, or the prostatic region. Two weeks later the urine was high as to color, specific gravity 1.026, free from albumin. The urine remained free from albumin four weeks later. Specific gravity 1.025. In testing for sugar at this time, using Fehling's solution, an intense rose-red color, resembling that characteristic of Piotrowski's (biuret) reaction for proteoses and peptones, was observed. The small remaining portion of the urine was saturated with ammonium sulphate and filtered, and the filtrate tested by the biuret test with a positive result. I therefore concluded that it was a case of peptonuria, but as the patient was perfectly well, no opportunity for further investigation was afforded me.

This case came under my observation many years ago, and the treatment with ammonium sulphate was not as rigid as we now know it should be for the thorough separation of albumoses. I do not, therefore, feel certain at the present time, that it was not a case of albumosuria (deutero-albumose). I report the case as the only one in my experience in which I have had any reason for suspecting the presence of true peptone, and also as an introduction to some remarks upon the subject of true peptonuria.

It is the prevailing belief that albumin is the chief simple proteid occurring in the urine, and the one which possesses the greatest importance, clinically. It is, however, a well-recognized fact that the urine may at times contain other simple proteids in solution, namely, globulins, particularly serum-globulin, proteoses, and possibly peptones. There is, at the same time, a noticeable lack of exact information relative to the frequency of the occurrence of these proteids. I have accordingly undertaken to utilize the large number of specimens to which I have access, for the purpose of obtaining, if possible, more exact information upon this point. The progress of an investigation of this nature is necessarily slow, owing to the difficulty in obtaining a sufficient number of suitable cases, as well as to the care and time required in testing for this class of bodies. This paper is presented as a preliminary communication and is confined to the consideration of globulinuria and peptonuria.

GLOBULINURIA.

Paraglobulin or serum-globulin is a representative of a class of proteids which resemble the albumins in undergoing conversion to coagulated proteid under the influence of heat or concentrated nitric acid. Accordingly in the examination of the urine for proteid by either the heat or nitric-acid test, no distinction is made between the two. Either or both, if present, are reported as albumin; a procedure which has found its justification hitherto in the assumption that both possess the same clinical significance. The globulins resemble the albumins in responding to the general color reactions of the proteids, and their solutions behave towards the general precipitants of the proteids, for the most part, as solutions of the albumins do.

The following are the important differences:

(1) Globulin is partially precipitated when a stream of carbon dioxide is passed through its solutions, which must be diluted more or less if the quantity of globulin is large.

(2) Globulin is insoluble in water, but soluble in dilute salt solutions. Consequently when solutions rich in globulin are poured drop by drop into a large volume of distilled water, the globulin is precipitated, because the percentage of salt is so far reduced by dilution, that it no longer suffices to hold the globulin in solution. The presence of globulin in the urine may frequently be detected in this manner. For the same reason, globulin is gradually precipitated from its solutions when the latter are submitted to dialysis.

(3) Globulin is completely precipitated when its solutions are saturated with magnesium sulphate or half saturated with ammonium sulphate. This property forms the basis of the only satisfactory method for the complete separation of globulin from its solutions. Half-saturation with ammonium sulphate is the more satisfactory method, since the precipitate thus obtained can be filtered and washed much more rapidly than is the case when magnesium sulphate is employed as the precipitant.

The process is carried out as follows: 25–50 cubic centimetres of the urine are made neutral or slightly alkaline with ammonium hydroxide, and the precipitated phosphates removed by filtration. An equal

[1] Read before the Boston Society for Medical Improvement, January 16, 1899.

volume of a saturated solution of ammonium sulphate is then added, the mixture shaken, and allowed to stand for some time, and finally filtered. The precipitate is washed with a half-saturated solution of ammonium sulphate for the removal of the last traces of albumin, and the filtrate and precipitate tested for albumin and globulin respectively, as previously described. The formation of a precipitate upon the addition of either magnesium or ammonium sulphate is not in itself evidence of the presence of globulin.

In testing the urine for globulin, the necessity of the preliminary neutralization with an alkaline hydroxide should never be lost sight of. Ott[2] has shown that in strongly acid albuminous urines saturation with magnesium sulphate effects the precipitation of a portion, and in some cases the whole of the albumin together with the globulin; and that the albumin remains wholly unprecipitated only when at least half the total phosphoric acid of the urine exists as a neutral phosphate. Pohl[3] also finds that the same holds true when ammonium sulphate is used as the precipitant.

Using the process above described, I have, thus far, analyzed the urine in 73 cases of acute and chronic Bright's disease, secondary renal hyperemia and local inflammatory affections of the urinary membranes; all cases in which the urine contained one-eighth per cent., or more, by weight of coagulable proteid. Globulin was found present in every case.

The case which introduces this paper was the only one in which globulin was the sole proteid. The quantity of globulin found has been very variable, usually ranging between 2 and 40 per cent. of the total proteid present. In 11 cases a trace only is noted. The largest quantity, 50–55 per cent. of the total proteid, was found in three cases of acute nephritis, in which the urine contained considerable blood, the result of an acute exacerbation. In an advanced case of chronic diffuse nephritis the globulin formed 46.5 per cent. of the total proteid present.

I have not observed any uniformity in the absolute or relative quantity of globulin in the urine of the same pathological condition. For example, in the three cases of acute nephritis just referred to, the globulin fell to a trace, 8.5 per cent. and 22 per cent. respectively, upon the disappearance of the blood. These results, so far as they relate to the frequency of the occurrence of globulin, agree with those previously obtained by Senator and by Paton.

Senator,[4] although using a process which is lacking in delicacy (precipitation by carbon dioxide), detected globulin in all the albuminous urines examined by him, and concluded that globulin invariably accompanies albumin. He found the largest quantity of globulin in the urine in six cases of amyloid disease. Globulin was abundant in the urine of acute nephritis, while the quantity was slight in cases of chronic diffuse nephritis.

Paton[5] also examined the urine in cases of acute and chronic Bright's disease, amyloid disease and functional albuminuria, and concluded that globulin always accompanies albumin. He found that the globulin varied greatly in quantity: between 2 and 60 per cent. of the total proteid. In one case of heart disease the urine contained albumin alone. He further found that the ratio of the globulin to the albumin varies so much through the day that no conclusions can be drawn unless the total urine for the twenty-four hours is examined. He ob erved that food has a great influence on the relative pr portion of the two proteids, a rich proteid diet appearing to cause an increase in the quantity of albumin excreted, especially noticeable on a milk diet.

Petri,[6] on the other hand, examined the urine in 41 cases of albuminuria, and found globulin in 13 only.

Estelle's[7] results are unique. He frequently met with cases in which globulin was the sole proteid present in the urine; and he further found that globulin invariably exceeded albumin in quantity in urines which contained both proteids. In two cases of chronic Bright's disease globulin amounted to 61 and 68 per cent., respectively, of the total proteids of the urine. His results were published before the importance of the neutralization of the acidity of the urine as a preliminary to the precipitation of the globulin was known, and are, for this reason, probably untrustworthy.

Führy-Snethlage[8] found the largest quantity of globulin in the urine, namely, 45 per cent. of the total proteid, in a case of interstitial nephritis with fatty degeneration. In two cases of amyloid disease the globulin amounted to 37 and 25 per cent., respectively, of the total proteid. He observed no uniformity in the quantity of globulin present in the urine of the same pathological condition.

Patella[9] also failed to observe any constant ratio between albumin and globulin in the urine in the different forms of albuminuria.

The statement is made in a text-book recently published (1896), that "so far not one case of pure globulinuria has been reported." Such cases have, however, been observed and reported, but the number is small. Maguire[10] has reported three cases of functional or physiological albuminuria, and one case of puerperal albuminuria in which globulin was the sole proteid present in the urine. Werner[11] also has reported a case of acute nephritis in which globulin was the only proteid present in the urine. Boyd observed a case of Bright's disease in which the urine contained globulin and albumose, but no albumin.

The following conclusions appear to be well founded:

(1) Albuminous urines contain also globulin in the great majority of cases.

(2) Globulin occurs in a small proportion of cases as the sole coagulable proteid of the urine.

(3) The same statement is probably true of albumin.

The significance of globulin as a constituent of the urine, and its value, if any, in diagnosis or prognosis, are unknown. There is, however, some basis for the belief that an increase of the proteid quotient (that is, the number obtained by dividing the quantity of albumin excreted in the twenty-four hours' urine by the quantity of globulin) is a favorable indication, a decrease, an unfavorable one. Hoffman[12] found that the proteid quotient is a fairly constant number, provided no marked change takes place in the condition of the patient; but that it always increases as the condition of the patient improves. In five cases reported by him there was a rise from 2.78 to 6.51, from 5.98 to 10.31,

from 7.13 to 13, from 3.7 to 6, and from 1.11 to 4.47. He maintains that the proteid quotient is not dependent upon the histological change in the kidneys, but that it is influenced particularly by the intensity of the pathological process.

Csatáry [13] also finds that an increase in the proteid quotient continuing over some days is a favorable symptom, while a diminution is unfavorable. He maintains, however, that the quotient is dependent particularly upon the rapidity of the circulation in the glomeruli, and not upon the form or intensity of the pathological process, or upon the state of nutrition of the patient.

Both albumin and globulin are constituents of the blood, and there is nothing surprising in the fact that both find their way into the urine. At the same time, their occurrence in such variable proportions, and especially the occasional occurrence of one alone, suggests the existence of some condition or conditions which influence the relative amounts of the two proteids excreted. The subject seems to me to be one worthy of further investigation.

PEPTONURIA.

True peptones, in the sense in which the term is used by Kühne, are the final proteid products of the hydrolysis of proteids. Proteids undergo this conversion physiologically, in the process of digestion. The same change is also effected through the agency of dilute acids at a suitable temperature, superheated steam and putrefactive bacteria.

Peptones are very soluble in water, and non-coagulable by heat or nitric acid. They are characterized by their diffusibility, a property which is also shared to some extent by the proteoses. In common with the proteoses, they give the rose-red biuret reaction with an alkaline hydroxide and solution of sulphate of copper. They differ from all other simple proteids in their non-precipitation by acetic acid and potassic ferrocyanide, and are especially characterized by the fact that they are not precipitated from their solutions, whether neutral, acid or alkaline, by saturation with ammonium sulphate. According to Chittenden, the latter reaction constitutes the main, and perhaps the only absolute, method of separating peptones from proteoses.[14] The literature of so-called peptonuria is very extensive, but it may, for the most part, be dismissed from consideration in this connection. A study of the numerous cases which have been reported in the journals shows conclusively that in many of these the characteristic proteid constituent of the urine has not been true peptone, but some form of proteose. In many cases faulty methods of analysis have been employed, and one is therefore left in doubt as to the true nature of the proteid, whether proteose or peptone.

This condition appears to find its explanation in a disposition to adhere to the old nomenclature, and to employ the term peptone either as synonymous with the so-called propeptone of earlier years, which is simply a mixture of proteoses of variable composition, or even to employ it in a more general sense, as it was formerly employed, to include all the products of digestion after the stage of acid proteid; in other words, to include both proteoses and peptones.

It is, I believe, a fact that there is at the present time no record of an authentic case of true peptonuria.

[13] Jahresbericht über die Fortschritte der Thier-Chemie, xix, p. 444.

[14] On Digestive Proteolysis, Cartwright Lectures for 1894, p. 63.

Senator [15] many years ago, before the distinction between proteoses and peptones was known, concluded that peptone exists in small quantity in every albuminous urine. More recently, however, he states that the proteids hitherto detected in the urine and reported as peptones are not true peptones, but albumoses.[16] According to Robitschek,[17] Kühne's peptone has never yet been detected with certainty in any animal organ or secretion. And Novy [18] states that there is probably no positive evidence that true peptone has been met with in fresh urine.

The occurrence and significance of peptonuria are, in fact, matters for future investigation. Moreover, the subject of albumosuria requires revision, for many cases have been reported upon the basis of very faulty methods of analysis. It is very important that, in future investigations of both albumosuria and peptonuria, the method of analysis employed shall be one which shall distinguish absolutely between these two proteids. The following method meets this requirement: The urine, freed from albumin and globulin, if present, by slightly acidifying with acetic acid, boiling and filtering while hot, is saturated with ammonium sulphate for the precipitation of the proteoses. This part of the process must be carried out with great thoroughness in order to effect the separation of the last traces of deutero proteose, if any is present. This is a form of proteose which stands near the peptones in its properties. According to Kühne,[19] it is not completely precipitated by saturation with ammonium sulphate unless the solution is boiled for a long time, and even then it may be necessary for complete precipitation to make the reaction of the liquid alternately neutral, acid and alkaline, and heat for some time after each change in the reaction. The precipitate, which may contain proteoses, urobilin and urates, is reserved for examination for proteoses. In the filtrate peptone may be detected by the biuret test, provided the urine is a practically colorless one. Otherwise the test cannot be applied directly, with reliable results, owing to the disturbing influence of the urinary coloring matters. In some recent experiments, using a specimen of Witte's peptone which was composed almost entirely of albumoses, I found that the biuret test, applied directly to urines of average color, did not respond with less than two to two and a half grammes of the peptone to the litre.

Chittenden [20] recommends the following process as perhaps the most satisfactory for the separation of the peptone from the ammonium-sulphate-saturated solution. The fluid is concentrated somewhat and set aside in a cool place for crystallization of a portion of the ammonium salt. The fluid is then mixed with about one-fifth its volume of alcohol, and allowed to stand for some time, when it separates into two layers, an upper one rich in alcohol, and a lower one rich in salts. The latter is again treated with alcohol, by which another separation of the same order is accomplished. The lighter alcoholic layers containing the peptone are united and exposed to a low temperature until considerable of the contained salt crystallizes out. The fluid is then concentrated, and after addition of a little water is boiled with barium carbonate until the fluid is en-

[18] Laboratory Work in Physiological Chemistry, p. 186.

[19] Chittenden's Digestive Proteolysis, p. 63, from Zeitschr. f. Biol., xxix, p. 2.

[20] On Digestive Proteolysis, p. 64.

tirely free from ammonium sulphate. Any excess of baryta in the filtrate is removed by cautious addition of sulphuric acid, after which the concentrated fluid, reduced almost to a syrupy mass, is poured into absolute alcohol for the precipitation of the peptone.

The precipitate obtained with ammonium sulphate, and which may contain proteoses, urobilin and urates, is washed first with a saturated solution of ammonium sulphate, then with alcohol containing a little chloroform for the removal of urobilin, and finally dissolved in water and the solution thus obtained tested by the biuret test.

Halliburton and Colls [21] have suggested the possibility of the formation of proteoses and peptones from the albumins and globulins in the process of separating the latter by heat after acidification with acetic acid. This has never occurred in my work, and I do not believe that any appreciable quantity of proteose or peptone is likely to be formed in this process. By means of the method just described I have thus far examined the urine in 23 cases. In no case was true peptone found. Albumose was detected in two cases. One was a case of pneumonia, in which the urine was analyzed two or three days before the death of the patient, and found to contain much albumose, with a trace of albumin. The other was an advanced case of diffuse nephritis. The urine contained albumin and globulin, with a trace of albumose.

So far as I can learn, true peptonuria has not yet received much attention at the hands of investigators. Schulter [22] examined the urine in eight cases of pregnancy, and in eight other cases (nephritis, pulmonary tuberculosis, scarlet fever, intermittent fever, pneumonia, carcinoma), and failed to detect true peptone. Senns [23] examined the urine in a variety of affections, in which there was suppuration, or destruction of tissues, and found at times albumose, but never true peptone.

Sior [24] could never detect true peptone in the urine of children, and also maintains that fresh pus never contains true peptone. If, however, pus is exposed to the air for some days true peptone is formed from the other proteids present.

On the basis of these few researches, we are unable to form any opinion as to the frequency of peptonuria as a symptom. I have presented these brief remarks for the purpose of calling attention to the present state of our knowledge of this subject, and I desire particularly to emphasize the importance of observing greater exactness in nomenclature in the future. Cases of albumosuria should be reported as such, and not as cases of peptonuria or propeptonuria, as has been the case in the past. The term peptone should be used to include those proteid products of proteolysis only which are not precipitated by saturation of the liquid containing them with ammonium sulphate.

LEPROSY IN CUBA. — According to the *Journal of the American Medical Association*, in several of the principal cities of Cuba there have been asylums for lepers who resorted to them voluntarily, but without strict isolation; during certain hours of the day the inmates were free to go in and out as they pleased. The sanitary authorities of Havana have now forbidden the lepers to leave the asylum.

OSTEO-ARTHRITIS OF THE SPINE: SPONDYLITIS DEFORMANS.[1]

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE term osteo-arthritis is used to designate the disease of the articulations which is characterized pathologically by a marked proliferation of the edges of the articular cartilage, associated with an atrophy or degeneration of the cartilage at the points of pressure, the two conditions producing an amount of impairment of function of the joint varying from the slightest inconvenience to complete anchylosis.

Various terms have been used to designate this condition, some of them suggestive of the general process, while others refer only to the local manifestation. Of the former, chronic rheumatism, arthritis deformans, rheumatoid arthritis, rheumatic gout, dry or proliferating arthritis, malum senile, arthrite sèche are the most commonly met with. Of the latter, the most common are malum coxæ senilis, referring to the disease as seen in the hip and spondylitis deformans, or spondylose rhizomelique, representing the same process involving the spine.

It is with reference to this latter manifestation of the disease that this paper is concerned, and while some mention of the general process is necessary, it will be only such as would be of value in considering the local disease.

The disease has been described by various writers in journal articles, but as yet there has been but slight mention of the subject in the works on orthopedic surgery, and most of the literature is devoted to the report of individual cases, with but little consideration of the disease itself. It is for this reason, and also because it seems to me from my observation that the disease is more common than has been supposed, that the subject is offered for discussion here.

Bradford in 1883 [2] reported three cases of "rheumatism of the spine," all in men between thirty and thirty-six years of age. In two practically the whole spine was stiff, with anchylosis of the ribs. In the other the rigidity of the spine was confined to the dorsal region. In the first two cases there was a gonorrheal history. In all of these cases the spine alone was affected.

Marie,[3] under the term spondylose rhizomelique, reports five cases of his own, in one of which there was a distinct gonorrheal history. One patient was sixty years of age, the others from thirty to forty, and in all some of the other joints, usually the hips or shoulders, were affected.

Strümpell [4] reports three cases, and in his book describes the type of painless progressive ossification of the spine and hips.

Mutterer [5] reports a case of a man fifty-eight years of age, with complete anchylosis of the spine, together with anchylosis of both hips and some slight trouble with the knees.

S. Popoff [6] reports a case of a man twenty-eight years of age in which the process developed very rapidly and was associated temporarily with weakness of the legs. This weakness disappeared as the disease became less active.

[6] Neurologisches Centralblatt, Jahrg., No. 7.

Beer[7] reports three cases, thirty-nine, forty-seven and forty years of age. In one a history of gonorrhea is given; in one the hips and shoulder-joints were affected; in another the shoulder and hand, and in one there is no mention of the other joints.

Marie and Astic[8] report a case of a man sixty years of age with trouble with the back of ten years' duration. The spine is completely anchylosed.

Bechterew[9] reports five cases: two women about fifty years of age, in both of which about half the spine was rigid, with no other joints affected. Of the three men, one, a patient thirty-nine years of age, had the spine completely anchylosed, with the symptoms of nerve pressure, such as areas of anesthesia and others of hyperesthesia. Other joints were not affected. Of the other two, one had paralysis agitans and the other was insane. In both cases the spine was rigid and there were symptoms suggestive of pressure upon the nerve roots. The other joints were apparently not affected.

Individual cases are also reported by Fagge,[10] Spillman and Etienne,[11] Gasne,[12] Raymond,[13] Sänger,[14] Stocker,[15] Henle,[16] Baumler,[17] Davies Colley,[18] Sturge,[19] and Pasteur.[20]

Of my own cases, ten in all, most of them have been seen in the Orthopedic Clinic (for adults) at the Carney Hospital, and the cases which have been selected are those which are particularly characteristic and in which the other joints have been but little if any involved.[21]

The first case was previously reported by me in the *Boston Medical and Surgical Journal* of December 26, 1895, and is here reported because of its relation to the other cases.

Case I. Mrs. McC., fifty-eight years of age, by occupation a nurse, had always been well and actively engaged in her work until the present sickness. Her family history is good, and she never had the least trouble from rheumatism. In July, 1893, she was caught in a thunder shower, and her clothing wet through. The next morning she complained of pain in the neck, with some tenderness in the upper part of the chest. There was no cough or expectoration. The pain in the neck increased in severity very rapidly, until the slightest motion caused the most intense suffering, and because of this she was admitted to the Good Samaritan Hospital. The patient entered the hospital in the service of Dr. Coolidge, and it was through his kindness that I was enabled to see her.

At the time of the first examination she was evidently suffering a good deal. The head was held a little to one side, the chin to the left, the shoulders drawn up, and all motions were most carefully guarded by muscular contraction. Any attempt at motion caused great pain. None of the other joints were in the least involved, and aside from this local condition the patient seemed well.

For the first week or two the patient was kept quiet in bed, and the various rheumatic remedies freely given with very little if any effect. After this a Thomas collar was applied for more complete fixation, and following this light-weight extension was used. These gave some relief, but neither could be used continuously because of the nervousness of the patient; so that the two appliances were used alternately, each being worn for a few hours. In three or four weeks after the beginning of the attack a swelling appeared in the right side of the neck. This was about the size of a small lemon, and was apparently connected with the spine. At the same time the numbness of the left arm was noticed, with some impairment of motion, and this condition continued and increased until the arm was almost entirely helpless. The right arm and both legs also became involved, never in as marked a degree as the left arm, but enough to make motion in bed, unassisted, impossible. At one time there was difficulty in swallowing, and for a short period breathing was almost entirely diaphragmatic.

The patient's condition remained about the same for two months, after which there was a slow but steady improvement, so that at the end of the third month she was able to sit up for a short time each day, and in December, five months from the onset of the trouble, she was able to move about with but little assistance, and was taken home. The paralytic symptoms referred to in the right arm and legs had by this time practically disappeared, but the left arm was still very helpless. The swelling in the neck was practically the same as when first noticed.

The patient was not again seen until thirteen months later, during which time, aside from the Thomas collar, no special treatment had been carried out. At the time of this examination the improvement in the patient's general condition was most marked. She moved about with perfect ease, and, aside from the stiffness of the neck and some impairment in the use of the left arm, she seemed well. Extension of the neck was entirely restricted, so that in order to raise the chin the whole body was bent backward. Rotation was also entirely restricted, while flexion was more free, it being possible to lower the chin to the chest. On each side of the neck, over the transverse processes, was very distinct thickening, apparently bony in character. In the left arm all motions were limited, especially those in which the shoulder muscles were used. The fingers were flexed, apparently due to the contraction of the palmar fascia and the flexor tendons. The sensation of the hand and arm was normal.

At the present time the patient's condition is practically the same as at the time of this last note. She is able to be about at her work, but there has been no change in the condition of the neck or arm.

Case II. Mrs. M., seventy years of age, came to the Carney Hospital over two years ago. She had considered herself, and had been considered by her family, to be well, until ten years ago. At that time she fell on the floor striking the lower part of the spine. Since then she has had more or less pain in the back, and while previously she had carried herself quite erect, she gradually bent over both to the front and to the side. Except the spine, the joints were not affected. At the time of the examination there was a large rounded kyphosis involving the whole dorsal and lumbar spine, together with quite marked lateral deformity. There was but little motion in the spine, and no symptoms of paralysis. Fig. 1 represents her condition at that time.

Case III. G. K., a man twenty-one years of age, a steel polisher by occupation, came to the Carney Hospital in June of 1897. For one year he had been having trouble with the back, with a gradual loss of the use of the arms and legs. At the time of the first examination the whole spine was bent forward and was rigid. None of the other joints were involved. The left arm could not be raised to the head, and both legs were very weak. The knee reflexes were present, the left being exaggerated. There was marked muscular atrophy of both arms and legs. The patient was seen by Dr. Bullard, and the diagnosis of osteo-arthritis with pressure upon the nerve roots confirmed.

Case IV. D. F., a man twenty-nine years of age, an ordinary laborer, came to the Carney Hospital in Septem-

ber, 1897. Some years previous he had an attack of rheumatism when in Ireland which lasted for three weeks. After that he came to this country and for a time "fired" in an engine-room. He used "to sit in draughts to get cool." This brought on another attack of rheumatism and he was unable to walk for seven weeks. The patient was well after the second attack of rheumatism until a few months ago, at which time he had typhoid fever. Soon after he was able to be about he noticed pain in the back, and as this increased and prevented him from working, he came to the hospital. At that time the spine was straight except for a slight prominence of the eighth, ninth, and tenth dorsal spines. The motions of the whole spine were guarded, but those in which the low dorsal vertebræ were used were least free. A plaster-of-Paris jacket was applied to prevent an increase of the deformity, and a little later this was changed to a leather jacket, which has been worn until the present time. There has been some bending forward, as is shown in the photograph, Fig. 2, and his spine has gradually anchylosed, so that at present it moves as one piece from the pelvis to the lower part of the cervical region. The ribs have also become anchylosed, so that the respiration is entirely diaphragmatic. His general health is good and except for an occasional few days of pain in the feet the other parts of the body have not been involved.

Case V. P. B., a man twenty-four years of age, came to the Carney Hospital in the early part of this year. His previous history was good and there was no history of rheumatism in the family. His work was that of stationary engineer, having charge of a hoisting engine, and, being obliged to work in all kinds of weather, he was much exposed. Five years ago he noticed pain in the back and feet for a time, but has been regularly at work until the past year. Since then he has been so weak and tired so easily that he could not work. When seen at the hospital the whole back was arched forward as shown in Fig. 3, and there was complete anchylosis from the pelvis to the mid-cervical region. The ribs were also anchylosed so that the breathing was wholly abdominal. The other joints were not involved and there were no signs of nerve pressure. The chief complaint was pain in the small of the back, due undoubtedly in part to the active disease, and partly to the muscular fatigue resulting from the posture. For treatment, aside from general remedies, the patient has worn a light spring-steel brace with much benefit.

Case VI. J. S., a man twenty-five years of age, came to the Carney Hospital in March of this year. For occupation he had done "firing" in a gas house and has considered himself well until the past three or four months, since which time he had had pain in the feet followed by pain in the hands and spine. At the present time the whole spine from the pelvis to the mid-cervical region is rigid, and the ribs also are anchylosed, so that the breathing is wholly abdominal. A few of the small joints of the hands and feet are involved. The spine is fairly erect, there being but little of the anterior bending.

Case VII. G. H., a man thirty-two years of age, consulted me in September, 1898, at the request of Dr. H. W. Cushing, of Johns Hopkins Hospital. The patient was a professor in one of our large universities. His family history was excellent, he had been well previous to January, 1897, when he broke down nervously. He went abroad, and soon after this, stiffness of the neck and shoulders developed, not enough, however, to prevent his going about. Soon after this, numbness developed in the left arm, with marked loss of power, and later the right arm was similarly involved, only not so severely. The condition improved slightly and then remained about as it was at the time of the examination. At that time there was a moderate rounded curve involving the upper dorsal and cervical regions of the spine. This portion of the spine was rigid. The shoulders were drooped forward and there was marked atrophy of the muscles of the chest, shoulders and upper back. Both shoulder-joints were somewhat involved, so that the motions were limited, and there was some thickening about the head of the humerus. On attempted motion there was marked spasm of the muscles about the shoulders and upper spine. The legs were normal and there was no change in the reflexes. There was a distinct loss of power in the left arm, with some numbness, and there was a tendency to the same condition on the right side. The treatment, which has been almost wholly general, has been followed by improvement.

Case VIII. C. H., a man sixty-two years of age, was referred to me by Dr. Geo. Bancroft, of Natick, in April last. When in the Civil War the patient contracted "rheumatism," and the back has been stiff ever since, so that he has not been able to work regularly. The neck has not been involved until the past eight months, previous to which time he overworked and broke down. Since this time the neck has been painful and has been growing worse. When examined the whole lumbar and dorsal spine was anchylosed and free from pain. The cervical region could be moved but slightly, and this only with great pain. Even the atlas and axis were apparently involved, there being but a very few degrees of motion of the head in any direction. The ribs moved slightly on respiration. The sensation in the right arm was much impaired, but the muscular strength remained about the same as the other side. The other joints were not involved. A Thomas collar to support the head gave very marked relief in this case.

Apparently in this case there have been two separate attacks of the disease — one early in life, and the other one thirty years later.

Case IX. M. J. K., a man thirty-four years of age, by occupation a currier, was seen by me at the Massachusetts General Hospital with Dr. John Homans. The patient had been well previous to five years ago. At that time he had an attack of pain in the shoulder, the left knee, and the right foot. Soon after this he noticed that his back was somewhat stiff. Three years ago the pain became acute in the right heel and since then this has caused him the most trouble. One year ago he had another attack of the so-called rheumatism, in which the neck was affected. He was in bed at that time for six months, and since then the back has been much stiffer and it has been difficult for him to breathe freely.

When seen by me he was well-nourished and developed. The spine was straight and was anchylosed from the pelvis to the cervical region. The ribs moved but slightly with respiration, the breathing being almost entirely abdominal. The other joints were in fairly good condition except the right heel, which was painful, and the x-ray picture showed a similar osteo-arthritic process. The position of the spine is shown in Fig. 4, and is interesting as showing that the rounded back is not necessarily characteristic of the disease.

Case X. Mary S., thirty five years of age, came to the Carney Hospital about three years ago because of trouble with the back and neck. The history as given was that a few months previous she made a change in the underclothing and took cold. This was followed by a sudden pain in the neck which prevented her from being about. At that time the slightest motion of the head was extremely painful. No other joints were involved. The arms for some time could not be used freely, the left one being the worse. Under general treatment the patient gradually improved so that at the present time, except for the rigidity of the upper dorsal and the lower half of the cervical spine, she is well.

In all about 35 cases have been reported previously, or 45 cases, including the 10 of my own. Besides this there have been several reports of pathological specimens, illustrating the pathological appearance of the disease entirely apart from the clinical history.

In analyzing such a series of cases certain facts are at once suggested, but before they can be studied to much advantage they must be distinctly differentiated from the other type of rheumatoid disease, which is chronic in character and also leads to joint anchylosis,

but in which there is atrophy of all the joint structures with no tendency to nodular growth or osseous deposit, as is seen in the type of disease under consideration.

Both of these diseases are usually considered together in the text-books under the head of arthritis deformans, which accounts for the variation in the clinical picture as it is presented by the various writers.

As the cases are seen side by side there cannot be the slightest question but what there are two distinct diseases, or two very widely divergent types of the same disease, and it is because of this that much of the confusion has arisen.

In a paper published in the *British Medical Journal* Bannantyne and Vollman have carefully described the two types, and in a paper entitled the "Treatment of Joints disabled by the so-called Rheumatoid Diseases," published by the writer in the *Boston Medical and Surgical Journal*, January 29, 1897, the two types were described and illustrated. In that paper the descriptive term "arthritis deformans" was used to designate the whole class of these so-called rheumatoid diseases. Rheumatoid arthritis was used to designate the cases in which joint inflammation and atrophy, resulting in anchylosis and marked distortion, were the chief features, while osteo-arthritis was the term used for the cases in which the nodular deposits about the articulations were the most prominent features.

The importance of this differentiation is mentioned because several of the cases which have been published as spondylitis deformans are undoubtedly cases of rheumatoid arthritis, and are not osteo-arthritis, which explains the discrepancy in the clinical picture.

It is evident, in the first place, in the analysis of the cases that the disease is essentially a disease of adult life, but not necessarily a disease of old age, as is often stated. Some of the worst cases have developed in the period of late adolescence, while in very few has the process started in old age. The disease as it is seen in old age is not so definitely localized in the spine, but, as a rule, the other joints are also more or less involved.

Another feature which is also noticeable is that there is no one cause or definitely recognized etiology to explain the onset. Gonorrhea has been mentioned as a probable cause in a certain number of instances, but in a much larger number this is not suggested as a possibility. In the majority of cases the cause seems to be some exposure or the rapid change in temperature of the affected part. These influences are recognized and accepted as etiological factors in similar phenomena in other parts of the body, and their importance in spondylitis deformans is probably equally certain. Exposure to wet or cold, or occupations which necessitate sudden changes from heat to cold, such as "firing" or "engineering" are the causes most frequently met with. Bechterew suggests trauma and heredity as possible causes. Beucke believes the process to be due to senile and mechanical causes.

Most of the other writers, however, either do not express an opinion as to etiology, or else accept exposure and gonorrhea as most probable.

Still another thing which is evident is that the disease is not peculiar to this generation, and that it also is not peculiar to the human race. Bland Sutton reports a specimen illustrating this disease in a mummy taken from the pyramids, while Sutton reports the disease in oxen and horses, and Bricon mentions a similar condition in cats.

Pathologically the disease consists of a nodular enlargement of the edges of the articular cartilages, with the subsequent ossification of these nodes and an extension of the process into the ligaments which have their origin or insertion near by. With this hypertrophy at the edges of the cartilage the centres or areas of pressure usually undergo atrophy. In the atrophy the interstitial tissue is the last to be absorbed, which explains the granular appearance as it is seen at times, but as the process continues this interstitial substance is absorbed, and either the two surfaces of bone fuse or remain in apposition. In the other joints in which there is free motion the bare surfaces of bone frequently become polished and increase in density.

The process in the spine usually begins upon one side anteriorly and extends up or down along the anterior lateral ligament. It may remain as a comparatively local process involving only a small portion of the ligament, as is shown in Fig. 5 and Fig. 6, or it may cross over to the other side and extend up and down until the whole spine is invaded. When this occurs the chief deposit or new formation of bone is along the lateral ligament, the change in the median line consisting simply of a fusion of the vertebræ, as shown in Fig. 7 and also Fig. 8, in which the lumbar spine had become joined to the sacrum.

At times, even though the hypertrophic change is quite active, that which develops from adjoining vertebræ does not fuse and a more or less free joint remains. This is distinctly shown in Fig. 7 and also in Fig. 9, in which an intermediate joint remains mobile (*a*), even though the osseous deposit has been so extensive as to entirely overlap the articulation in front (*b*).

As the disease goes on in the ligaments and cartilages the intervertebral substances atrophy, and if the process is slow the entire intervertebral disc may be absorbed before anchylosis takes place. If this be the case naturally the back is rounded and the spine becomes very much arched, as shown in Fig. 10. If, on the other hand, the process is more active the vertebræ may become anchylosed before the disc has been absorbed, and consequently no deformity is produced. If this be the case the disc ultimately is replaced by osseous tissue and the anchylosis rendered more complete. The condition is shown in Fig. 9. If the process is more active on one side than the other it is easy to see that lateral deformities may result and naturally this is more commonly seen in the cervical region, where the spine has more flexibility. The condition is well shown in Fig. 11.

While these changes are taking place in the anterior portion of the spine, similar changes take place in the ligaments and articulations at the back, so that the transverse and rarely the spinous processes are affected. It is the disease in these regions that causes most of the symptoms of paralysis or disturbed sensation, by narrowing the foramina through which the spinal nerves pass.

Clinically, as the disease is seen, the subjective symptoms are usually slight in comparison to the actual pathological change, and frequently there has been so little trouble with the back, and the change has taken place so gradually, that the patient is not conscious of any special limitation, the condition being discovered by accident. More often, however, there is considerable pain, which is referred to the back and which is aggravated by change of position. When quiet the

pain is so much relieved that the patient frequently does not seek treatment until the disease is far advanced, or even if treatment is asked it is often excused without examination as a "touch of rheumatism" and the therapeutic suggestions made accordingly.

If the disease is seen early, before much actual change has taken place, there is usually a definite region in the spine to which the pain is referred, and in this region the motions are restricted, at first, of course, by muscular spasm, but later by osseous change. At this time, when the process is so definitely localized, the portion of the spine affected may appear more prominent than normal, suggesting the beginning deformity of Pott's disease, and at this time a positive diagnosis may not be possible. The onset is suggestive and also the reference of the pain to the back at the exact seat of the disease rather than the referred or abdominal pain of Pott's disease, but it may require some weeks before the true nature of the process can be determined. Case IV was at first thought to have Pott's disease, and it was only after seeing him several times that the correct diagnosis was made.

As the anchylosis of the spine takes place the ribs almost invariably are affected, and the process may prove so extensive that all the articulations become anchylosed, and the thorax is perfectly rigid. In this case thoracic respiration is of course entirely lost and the breathing is done wholly by the diaphragm.

Beside the pain in the back and the limitation of motion, neuralgic pains in the arms or legs, together with disturbances of sensation, numbness or hyperesthesia, are probably the most common symptoms. These are, of course, due to pressure upon the nerve roots, and consequently are not seen until the disease is well advanced, or when the onset has been unusually rapid, as in Case I. Following these neuralgic pains, when the disease is well advanced, paralysis may result, the extent of which varies from complete inability to use the part to a slight inconvenience. Rarely are the two sides affected equally, or if both sides are affected the symptoms have developed at different times. This, together with the fact that the paralysis is peripheral in type, is of importance in differentiating it from Pott's paraplegia.

Occasionally, when the disease is very active, the same osseous deposit takes place in the posterior ligament (*ligamentum longitudinale posticum*), and may result in enough narrowing of the spinal canal to produce symptoms of pressure paralysis, exactly similar to that seen in connection with Pott's disease. This is not very common, but nevertheless does occur and must be borne in mind in making the diagnosis. Case I had this type of paralysis in connection with the paralysis of the arms, due to the pressure upon the nerve roots. The presence of the two types of paralysis is of assistance in determining the diagnosis.

After the active stage of the disease has passed, with the lessened vascularity and natural shrinking of the non-osseous structures the direct pressure upon the spinal cord is usually relieved and the same may be true of the pressure upon the nerve roots. In my own experience, and so far as I can learn from the reported cases, there is no case in which the symptoms due to the direct pressure upon the cord have not been relieved. With the involvement of the nerve roots, while there has always been some improvement, in many of the cases the recovery was never complete.

The deformity, which is so striking at times, has a wide range of variation. In the most extreme form the rounded back with the protruded head and the flat chest (Fig. 3) is the type usually pictured or described. It is evident, however, that the nature or extent of the deformity must vary with the seat or extent of the disease, and also with the rapidity of its development. In Case IX, Fig. 4, the whole dorsal and lumbar spine is anchylosed, with scarcely any change in the normal curves.

The lateral deformity of such an extreme type as is shown in Fig. 1 is rarely seen, and probably could only occur late in life. The deformity is probably due to osseous deposit and thickening on one side of the spine, with atrophy and softening on the other side. A moderate amount of lateral deformity is not uncommon, and is almost always present when the disease is in the cervical region.

The treatment of this disease is of more importance than is commonly supposed, and is partly medicinal and partly mechanical. As an early diagnosis is, of course, of the first importance, it is at this time, before the deformity has taken place, that the most can be accomplished. The disease is probably a trophic process and consequently all medicines or methods of treatment which debilitate should be most carefully avoided. This naturally includes the various so-called rheumatic remedies, all of which are depressants, and also the various baths or courses of treatment which tend to lower the vitality. The general treatment should be wholly nourishing and stimulating. Extra diet, stimulating bathing, massage of the unaffected parts, electricity in a mild current, all are of value, and also the dry heat, provided it is not used so frequently as to be debilitating, relieves the pain and does much good. For medicines, iron, arsenic and strychnia are the drugs which are of the greatest value. Cod-liver oil and alcohol in medicinal doses are also useful. For mechanical treatment some form of spinal support should be used at once, partly to relieve the pain by restricting the motion, and partly to prevent the marked deformity from developing. Case IV was under treatment quite early in the disease and even with the imperfect general care which it was possible for him to have he has been kept from becoming more deformed than is shown in his picture (Fig. 2). A plaster-of-Paris jacket was used at first, and this was followed by a leather jacket, which is still worn. The whole spine has been involved and also the articulations with the ribs, and I am sure that without treatment the deformity would have been as great as that shown in Fig. 3. The position of the chest, with the greater room for respiration, has had a very definite beneficial effect upon his general health.

Manipulation of the spine is naturally of little value, and probably would result in more harm than good. Attempts have been made to forcibly break up the anchylosis,[22] but they have been followed, as would be expected, by results which were not satisfactory.

The Plague in India. — At Poonah, a city on the railroad from Bombay, where the plague is raging with unusual fury, there were, according to the *Medical Record*, 210 new cases and 177 deaths during the last week of July. In all there have been 301 cases and 261 deaths. Several Europeans have died.

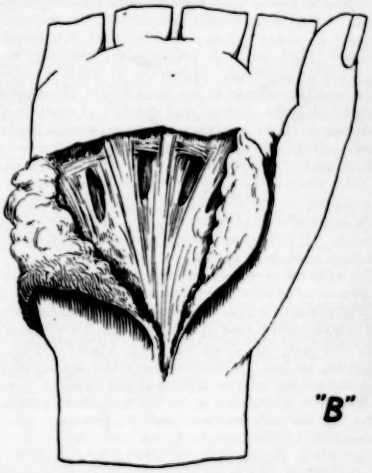
OPERATIONS IN THE TREATMENT OF PALMAR ABSCESS.[1]

BY W. A. BROOKS, JR., A.M., M.D., BOSTON.

As a rule, the operation upon a palmar abscess consists in making numerous short incisions through the skin over the metacarpal bones. The operation is simple of execution, and by allowing the greater part of the pus to escape greatly diminishes the danger of further extension of the suppurative process. It does not, however, give the surgeon a chance to see and examine the true condition of the structures in the palm. Even with the free use of the curette, it is lacking in thoroughness, owing to the fact that in the greater number of cases many pockets of pus remain undiscovered and unopened.

The post-operative treatment of cases operated upon by this method is unsatisfactory, for the reasons that the openings are so small that gauze drainage is likely to prevent free drainage rather than favor it, and the



removal and replacing the wicks during the daily dressing cause the patient considerable suffering.

The incisions themselves, owing to their number, location and direction in which they are made, are the cause of a great deal of the stiffness which is so commonly seen in the palms of patients who have had palmar abscesses operated upon by this method, as they leave scars which run at right angles to the natural folds and are generally firmly adherent to the deep structures. Such being the case it is next to impossible for the palm to fully regain its natural flexibility.

In view of these facts, any operation which would seem to offer the advantage of being more thorough, which makes the daily dressing less painful and tends to lessen the amount of subsequent stiffness, is worthy of consideration and trial.

For the past year I have used the following method of operating upon these cases, and the results have proved most satisfactory as compared with the results obtained by the old method. The operation consists in making a long incision following the natural furrows of the palm and in dissecting back the skin, thus converting the palmar bursa into an open pouch. The incision is commenced at the end of the transverse furrow, on the ulnar side, carried almost the entire length of the furrow, then carried across to the furrow which winds around the base of the thumb, and along this to the wrist. If necessary the incision can then be carried up the middle of the forearm. After the incision has been completed the skin is carefully dissected up from the palmar fascia and the flaps turned outwards.

With the palmar fascia exposed the whole area of the palm can be explored and the various pockets of pus can be seen and curetted. Free access is given to examine and, if necessary, open the tendon sheaths. There is little danger of cutting the larger vessels and nerves, for they can be seen and avoided.

After the operation is completed the bursa is packed with gauze which has been wrung out in hot bichloride solution (1–5,000). The skin flaps are allowed to remain outside of the packing. The whole hand is then done up in an antiseptic poultice.

As a daily dressing the poultice is removed and the whole hand, with the packing still in place, is put into a hot antiseptic bath for an hour or so. Either during the bath, or immediately after, the packing is easily removed and replaced without much pain.

After a week or two the structures in the palm become covered with bright red granulations. As soon as they appear the packing is no longer used, but the skin flaps are folded back and a dry dressing applied. Union takes place between the skin and the subjacent tissues. From day to day the edges of the flaps are drawn more closely together till they come to lie on nearly their original positions.

The diagram, "A," will give an idea of the course of the incision. The dotted line should have been made on the line of the furrows.

[1] Read before the Boston Society for Medical Improvement, January 16, 1899.

The second diagram, "B," shows how the flaps are to be turned back, and also shows how, by the splitting up of the palmar fascia, free access is given to the deepest part of the palmar bursa.

Clinical Department.

PRELIMINARY NOTE ON THE PROGNOSIS OF NEPHRITIS.[1]

BY RICHARD C. CABOT, M.D., AND FRANKLIN W. WHITE, M.D., BOSTON.

The material upon which this study is based was obtained as follows:

From the records of the Massachusetts General Hospital for the last twenty years, the course and symptoms of all fatal cases of nephritis were noted, and the duration of each case, from the time of the first symptom to death, was estimated as accurately as possible. In addition to this, circulars were sent to the address of every patient who had left the hospital between 1880 and the present day, suffering from nephritis of any type. By means of these circulars, we attempted to find out the condition of the patients since leaving the hospital, and the date of death in the fatal cases. Only a portion of those to whom circulars were sent returned an answer, but the answers received were very instructive. All of the cases diagnosed in the hospital records as nephritis who returned any answer to our inquiries were followed up as carefully as possible, and in many cases the urine was examined. The number of these cases, together with the fatal ones, is 332.

In addition to these, we have a considerable body of data, sent us with great kindness by a large number of physicians to whom we wrote, asking whether they had ever known a case of chronic nephritis to recover, and also how long they had ever known a case of nephritis to last. This data furnished us details of 191 more cases, making a total of 423 in all.

We were stimulated to make the above investigations by the indefiniteness and disagreement of the statements in the text-books on the subject of the Prognosis of Nephritis, especially in its chronic form. Many writers show a strong tendency to hedge when it comes to the question: "Does a case of chronic nephritis, properly certified as such, ever recover?" Thus, for example, Rotch, in his "Diseases of Children," says of the prognosis of chronic nephritis: "Some cases, having the clinical features of the disease, have apparently recovered." Delafield, in the "American System of Medicine," says, under Chronic Diffuse Nephritis, "Recovery seems to be possible." Osler says that in chronic parenchymatous nephritis, recovery rarely takes place in a case that has persisted for more than a year, but occasionally in children, even when the disease has persisted for two years, symptoms disappear and recovery takes place. Senator,[2] speaking of chronic diffuse nephritis, says that termination in recovery is a rare exception, but undoubtedly occurs. He agrees with Rosenstein that these are usually cases which, after acute onset as a result of infectious disease or exposure, become chronic, and after one and one-half or two years, end in recovery, the urine becoming entirely normal. An entire *restitutio ad integrum* of all the kidney tissue does not occur, but this is not indispensable for complete functional recovery. He also says that death is invariably the result in interstitial nephritis where the typical contracted kidney is developed, and the heart hypertrophy is marked. Recovery (functional) is possible, and under proper treatment is not rare in the first stage, that is, as long as no sign of heart or vessel lesion has developed.

Strümpell, in his last German edition, speaking of chronic diffuse nephritis, says that complete recovery undoubtedly occurs, but is rare. By the passage of the large kidney into secondary contraction "apparent healing" may occur, in which the subjective condition of the patient is almost entirely satisfactory. He considers chronic insterstitial nephritis incurable, though life may be prolonged without any considerable unpleasant symptoms for many years. Bartels, in "Zeimssens' Encyclopedia," says that chronic nephritis is incurable after a certain time, but that cases have recovered even after months of dropsy. On the other hand, Brault in the "Traité de Médicine," says that in chronic nephritis the future is always sombre; sooner or later uremia or a complication leads to a fatal ending. Tyson, also, and Loomis, in the "Twentieth Century Practice of Medicine," say that cases never recover. In Albutt's System, and in Fagge, no definite statements are made on this point.

Under these circumstances, with such variety in the opinions of the foremost writers, our interest centered about the question: "Does a case of chronic nephritis, certified as such, ever recover?"

At this point it seems best to define what we mean by chronic nephritis and by recovery.

(1) We recognize two important types of chronic nephritis: (*a*) Chronic diffuse nephritis, and (*b*) interstitial nephritis.

(*a*) By chronic diffuse nephritis we mean a disease characterized by prolonged anasarca and effusions into the serous cavities, early and pronounced manifestations of uremia, such as headache, vomiting, and dyspnea, vascular changes, such as cardiac hypertrophy and a high tension pulse, and a pale urine usually diminished in amount, containing a large amount of albumin, with an abundance of fatty elements in the sediment.

(*b*) By chronic interstitial nephritis we mean a disease of insidious onset and long course, with comparatively early appearance of the vascular changes above mentioned, and little or no edema until the heart fails, with late and usually less marked uremic symptoms, a large amount of urine of low specific gravity, with albumin present in very small quantities if at all, and a sediment containing usually only a few hyaline and granular casts.

(2) We consider a patient to have recovered when he has no subjective symptoms characteristic of nephritis, and passes normal urine.

Defining our terms in this way, we have now come to the analysis of our cases, and taking first the data from the Massachusetts General Hospital records, we find that of the total 304 cases in which a diagnosis of chronic nephritis stands recorded on the books of the hospital, and which we have been able to follow up till death, or till the present time, there are only 17 whose urine and general condition show that the patient has really recovered. In most of these cases,

[1] Read at the annual meeting of the Massachusetts Medical Society, June 13, 1899.

[2] Senator: Erkrankungen der Nieren.

although the diagnosis of chronic nephritis stands upon the books, it is difficult to see why it should have been made. From the facts recorded it was evident, in most of the cases, that the patient was rapidly improving, that the symptoms were of comparatively brief duration, and the diagnosis seemed unjustified. In a few cases, on the other hand, the long duration of the symptoms and the character of the urine indicate an undoubted chronic nephritis followed by a genuine recovery. The following two cases are among the more remarkable of our series:

Case I. Woman, age twenty-three years. Eight years ago symptoms of chronic diffuse nephritis lasting for two and one-half years, headache, vomiting, marked edema of body, face and legs, also ascites, which was tapped twice. Urine contained one-quarter to one per cent. albumin and many hyaline, granular and fatty casts. For the last six years she has been perfectly well and leading an active life. The urine examined a year ago and also this year was normal, free from casts and albumin.

Case II. Boy, age sixteen years. Chronic diffuse nephritis followed scarlet fever at the age of eight years, lasting for four and one-half years, with headache, vomiting and anasarca. The urine contained one-eighth per cent. albumin and many hyaline, granular and epithelial casts. He had several severe exacerbations. Has been perfectly well for three and one-half years and is now at work. The urine at the present time is perfectly normal.

In answer to the question, "Have you ever known a case of chronic nephritis to recover?" forty-eight of the physicians who were asked said no, and twenty-one (about one-third of the whole number) said yes. Among these latter answers are the following:

(1) Dr. J. M. Da Costa, of Philadelphia, writes of the case of a young woman, eighteen years of age, who had chronic parenchymatous nephritis of about a year's duration:

> The disease came on gradually, though there was a statement of its having followed exposure. Dropsy was a marked symptom. There was considerable albumin in the urine, and epithelial casts. She gradually recovered entirely, got married, and became the mother of five children. She was seen last year, and her urine was found to be perfectly normal.
>
> In a second case, twenty years of age, seen in consultation, the disease of the kidney followed scarlet fever at the age of eight. As a boy, he learned to test his urine for albumin, and continued to test it until he was grown up, with the result of never finding albumin absent, though not present in great quantity. He tested for it and found it only a few months before an exacerbation of the disease, coming on after exposure; in this the urine contained large amounts of albumin and tube casts. Under a rigid milk diet for three months, mild diuretic waters, iron, and other means, the dropsy disappeared, and his general condition greatly improved, but albumin remained. Pursuing treatment for two months more, the albumin gradually disappeared, and, though constantly tested for (and he was no longer on a restricted diet), none was found for some months afterwards, when he was looked upon as having entirely recovered. I never heard of a return of the disease.
>
> In a third case, in a man sixty years of age, who was dropsical for months, there was a history of the kidney disease having begun after exposure about two months before he came under observation. The urine was markedly albuminous and contained tube casts, but no blood casts or blood. Under treatment for ten weeks, the albumin was reduced to a trace, and for some little time was absent; but a few months afterward, during a period of great family distress, it was again found in the urine, though not in large amount. Under treatment it slowly disappeared, and, examining him three years afterward, not a trace of kidney disease could be detected. The patient subsequently died of phthisis, which was hereditary in his family.

(2) From Dr. Charles G. Stockton, of Buffalo, we received the following case:

> The case came under my observation in the autumn of 1890. The patient was a woman about forty-six years old, of medium height, and 240 pounds. The exact weight could not be ascertained. She had been in poor health for several years, and for the past six months had suffered from headache, dizziness, anorexia, mental confusion, irregularity of the bowels, and increased general anasarca. The aortic second sound was relatively intense and high pitched; the apex too far to the left, not palpable owing to the fat. There were no bruits. There was increased arterial tension.
>
> The first recorded examination showed about 12 per cent. albumin (by bulk), with hyaline, granular, and epithelial casts. A more complete examination was made a few days later when she voided, in twenty-four hours, 26 ounces of urine containing 27.4 grammes of urea and albumin about four per cent.
>
> Examinations were now made daily and it was found that the amount of albumin, by Esbach's method, was from two to four grammes per litre. The casts continued; sometimes the hyaline form predominated, at other times both finely and coarsely granular casts predominated, and occasionally large numbers of epithelial casts were seen. Under treatment on the 9th of January, 1891, only one-half gramme of albumin to the litre was found, and 1,136 cubic centimetres of urine were passed in twenty-four hours and the urea had risen to 30.67 grammes. This amount did not continue, and she had a number of relapses, judging from the condition of the urine. For instance, on the 14th of January there was in 1,408 cubic centimetres of urine two grammes of albumin per litre, and the same casts. On the 25th of January the urine had fallen to 768 cubic centimetres, 21 grammes of urea, two and one-half grammes of albumin per litre; no casts were found. On February 27th, albumin four grammes per litre, urea 29.23 grammes, a number of uric-acid crystals, hyaline and epithelial casts, and renal epithelium. On the 8th of March the urea had fallen to 19 grammes, albumin had risen to 4.50 grammes per litre; there were hyaline casts. On the 15th of March there were no casts found. Urinary examinations showed varying results, but on the whole about the same for some months thereafter. In September there were six grammes of albumin to the litre, 832 cubic centimetres of urine, 21 grammes of urea; no casts found. On the 11th of November a few casts, urea had fallen to 16 grammes. From this time on the casts decreased in number and were almost altogether hyaline, albumin varied. On November 19th there were five and one-half grammes per litre; December 12th, a few casts. January 3, 1892, urine 28 ounces, urea 22.4 grammes, hyaline, slightly granular casts. July 12, 1892, .75 gramme of albumin per litre, urea 22 grammes, pus corpuscles, epithelium and a few granular casts. December 6, 1892, more than two years after I first saw her, the albumin was .25 gramme per litre; one small granular cast. May 9, 1893, there was no albumin, urea 23.71, and no casts found. From this time on the urea was less in amount, the urine became more abundant; albumin was found in varying quantities, usually in traces only, and occasionally hyaline and slightly granular casts. For the past three years, I have found that the urine has been uniformly free from albumin and casts. The patient's general condition corresponded rather closely with the state of her urine. Her symptoms were somewhat promptly relieved by treatment, but there was more or less edema for at least a year after I first saw her. Her vision was disturbed in the beginning, but an eye examination showed that the retina was not affected. I have a report on the condition of the retina reaching back as far as 1888.

(3) From Dr. D. W. Prentiss, of Washington, the following note:

A case of chronic parenchymatous nephritis had been ill about six months when I first saw him. Diagnosis unmistakable; recovered in about a year. This was eighteen years ago. He is still well and has been working at his trade ever since. Theory of recovery: that but one kidney was affected.

(4) From Dr. G. Baumgarten, of St. Louis, the following:

In August, 1894, the patient had edema of the face and hands. In October, 1894, extensive anasarca was present; urine about normal in quantity, 1.015, one and one-half to two per cent. of albumin, granular casts, leucocytes, no blood. December 25, 1894, much better; anasarca about the same, urine one and one-half per cent. albumin, many casts. January, 1895, dropsy began to disappear; returned to work. May, 1896, feels well; urine 1.029, with a trace of albumin and few casts. April, 1897, excellent health; urine free from albumin and casts; has remained well to this day.

Other physicians who have known cases of chronic nephritis to recover are H. C. Wood and J. P. C. Griffith, of Philadelphia; Beverly Robinson, J. S. Billings, and G. L. Peabody, of New York; J. B. Herrick, of Chicago; E. L. Trudeau, of Saranac, and W. S. Thayer, of Baltimore.

In addition to our recovered cases there are nine patients who are at work and in good health at the present time, despite the presence of albumin and casts in greater or less quantity in the urine. The duration of these cases from the first symptoms suggestive of nephritis up to the present time is as follows: One for five months, two for five years, one for seven years, two for eight years, one for ten years, one for eleven years and one for twelve years.

Many of these latent cases were very striking. The people were able to work hard and steadily for years at a time without interruption, and were entirely free from any disagreeable signs or symptoms, while at the same time the urine contained a trace to one-quarter per cent. of albumin and an abundance of casts.

Among the cases of which notes were sent us by other physicians are the following:

Dr. Franz Pfaff, of Boston, says:

I have under observation a patient who has had nephritis for twenty-five years. The urine shows, as the result of repeated examinations, the following characteristics: amount 1,680 cubic centimetres; specific gravity 1.009; albumin very large trace; urea 1.13 per cent.: hundreds of casts in large slide, hyaline, fine granular, coarse granular, a few very highly refracting. Many of the casts are fatty and had renal cells adherent.

Dr. Wharton Sinkler, of Philadelphia, sends the following cases:

(1) Mrs. W. had puerperal nephritis and lived twenty-five years with it. The urine always contained albumin.

(2) Mr. E. has had nephritis for about twenty years. It began with an acute attack, with bloody urine. He is still in fair health, though the urine contains albumin.

Dr. Isaac Adler, of New York, sends the following:

I have under observation a case of chronic parenchymatous nephritis which has lasted for twenty-six years, and still shows but little disturbances of general health; no edema; no ascites. The urine contains, on the average, two per *mille* of albumin (Esbach), with granular and fatty casts.

Dr. Alfred Stengel, of Philadelphia, says:

I have under my care two physicians. One has had albumin, casts, and the general symptoms suggestive of chronic interstitial nephritis for ten years to my knowledge. He himself believes that he has had it for twenty years, having discovered albumin in his urine as long ago as that.

Another case which occurs to me is a lady who has had nephritis certainly for twelve years. Lately, there has been a little swelling of the feet, but this is the only symptom I have ever discovered suggestive of nephritis.

Dr. James Tyson, of Philadelphia, writes:

Recently I was asked for an opinion in the case of an army officer who had an acknowledged uremic convulsion twenty-nine years ago; returned to duty, and remained on duty until last summer, when he died of Bright's disease.

Two hundred and sixty-nine of our cases have died. The average duration of these fatal cases from start to finish was nineteen months. Forty of our cases lasted less than two months from the first symptom to the time of death. One hundred and fifty-two cases lasted from two months to two years, and 46 cases from two to five years. The longest cases in our series are seven, ten, twelve, fourteen, sixteen, twenty, and twenty-three years. Of the fatal cases, 210 were of the type of chronic diffuse nephritis under which we include those ordinarily classed as chronic parenchymatous nephritis; 52 were of the interstitial type.

In the list of 91 cases of long duration sent us by physicians, 27 had lasted from ten to fifteen years; 16 from fifteen to twenty years; and six over twenty years, namely: one, twenty-two years; three, twenty-five years; one, twenty-eight years, and one, thirty years.

The number of acute cases in our series was so small that it has seemed best to discard them. It is a notable fact, in this connection, that for the last five years the number of cases diagnosed as acute nephritis at the Massachusetts General Hospital has steadily diminished. We interpret this to mean that cases formerly called acute are now considered as an acute exacerbation of a chronic case.

RELATION BETWEEN ETIOLOGY AND PROGNOSIS.

The nine cases in which there was a distinct history of lead poisoning have generally run a comparatively long course. The same is true of the 16 cases in which syphilis occurred. Some of the shortest cases, if we are to judge simply by the duration of definite symptoms, were those associated with arterio-sclerosis, in which fatal uremia came on out of a clear sky and killed the patient within a week.

Curiously enough, the 57 cases in which the only possible etiological factor obtainable was heredity; that is, a family history of nephritis, dropsy, apoplexy, heart disease, or phthisis, seemed to run a relatively long course.

We were unable to observe any relation between the duration of cases and the occurrence of such etiological factors as abuse of alcohol, infectious diseases, pregnancy, or exposure to cold. In the vast majority of our cases no cause of any kind could be traced.

EFFECT OF COMPLICATIONS UPON PROGNOSIS.

Complications were the cause of death apparently in 44 cases out of our 332. Pneumonia and pericarditis were the most frequent of these and phthisis next. Pneumonia and pericarditis have occurred with about equal frequency, and our statistics indicate that pneumonia is equally common as a cause of death in cases

of short and of long duration, while pericarditis seems more apt to carry off a patient at a comparatively early stage of the disease. Thus of the 11 cases ending fatally with acute pneumonia, five cases had a duration of less than two years, and six cases of two years or more. On the other hand, only two of the 15 cases ending with acute pericarditis had a duration of two or more years.

As cases of nephritis get on past the first year the dangers of such complications as cerebral hemorrhage, hemiplegia, and gangrene increase.

RELATION OF DROPSY TO PROGNOSIS.

It has been said by good authorities that the prognosis in diffuse nephritis is worse in cases where dropsy is marked, but in 47 cases of our series, in which no dropsy occurred, the average duration was ten months, compared to twenty-three months, which is the average duration of the cases in which dropsy was present. In short, the course of the disease in the cases of diffuse nephritis without dropsy was less than half as long as in the cases with dropsy.

Dropsy is not sufficiently common in interstitial nephritis to be of much prognostic value.

RELATION OF RETINAL CHANGES TO PROGNOSIS.

Good authorities state that cases of chronic nephritis rarely last more than two years after the presence of hemorrhages in the retina. This is borne out by our series of cases, of which only one lived over two years from the time at which hemorrhages were seen in the fundus oculi. In this case, however, the patient lived five years and seven months, after the date at which retinal hemorrhages in both eyes were observed by Dr. Wadsworth at the Massachusetts General Hospital.

CARDIAC ENLARGEMENT AND PROGNOSIS.

Occurrence of hypertrophy of the heart is universally acknowledged as marking the advance of the disease beyond the curable stage. This is borne out by our statistics of the 104 cases in which cardiac enlargement was demonstrated. Only three lived more than two years from the date at which the enlargement was demonstrated.

We will summarize our conclusions as follows:

(1) Chronic nephritis is not an absolutely incurable disease. Recovery occurs in rare instances.

(2) Chronic nephritis may exist for a long series of years without causing any apparent constitutional disturbance.

(3) The average duration in 332 cases of chronic nephritis was nineteen months.

(4) Acute nephritis is less common than has been supposed; many cases formerly diagnosed as such have been shown to represent exacerbations in chronic nephritis.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, January 16, 1899.

DR. WM. A. BROOKS, JR., presented an

OPERATION FOR PALMAR ABSCESS.[1]

This was illustrated by a dissection, and a patient operated upon in the method described.

DR. M. H. RICHARDSON read a paper on

THE SURGICAL TREATMENT OF ESOPHAGEAL DIVERTICULA.

DR. W. B. HILLS read a paper on

THE PROTEIDS OF THE URINE.[2]

DR. WOOD: There is hardly anything to be said in addition to what Dr. Hills has given us in regard to the globulinuria and the so-called peptonuria. It has, of course, for a long time been well known that globulins have been present with serum-albumin in the urine of almost all cases of so-called albuminuria. There is one set of cases, which I did not understand Dr. Hills to include, in which one pure globulinuria was found in a series of 40 cases, and the statement has been made that the relative proportion of globulins increases as improvement takes place. This would make a very interesting subject to follow up, and I hope Dr. Hills will continue his work in that direction, particularly with acute nephritis, and in cases of simple improvement in interstitial disease of the kidney. One author has mentioned that the largest proportion of globulin was found in cases of interstitial disease of the kidney and in cases of passive congestion secondary to heart trouble. With reference to what has been called peptonuria, which Dr. Hills has shown us is very largely due to the presence of proteoses in the urine, the important point seems to me to be that this condition has been shown to be caused by the retrograde metabolism of the cell elements, and is found in cases of resorption of pus and in cases of extensive extravasation of blood, etc., and also in cases where any tissue whatever is undergoing unusual retrograde metabolism, as in subinvolution of the uterus, and in pneumonia, as reported by Dr. Hills. I would add that in the cases of true albumosuria, where there are large quantities of albumose present and of which I have seen three cases, the albumose appears to be, in both cases which have been investigated, very largely in the form of nucleo-albumose. The albumose in those cases has contained a very large proportion of phosphorus.

DR. HILLS: I think Dr. Wood referred to certain cases of hyperemia dependent upon heart disease. Those cases, if I remember correctly, were reported by Maguire, and I did not call particular attention to them, because other investigators, Paton for instance, were not able to confirm the observation. I remember the fact as you suggest it.

MAINE MEDICAL ASSOCIATION.

FORTY-SEVENTH ANNUAL MEETING, HELD AT BANGOR, JUNE 7 AND 8, 1899.

THE Association met in the Common Council chamber of the City Building at 10.15 A. M., Wednesday, June 7th, the President, DR. C. O. HUNT, of Portland, in the chair. Prayer was offered by the REV. C. H. CUTTER, of the First Parish Church.

The Treasurer's report showed the usual satisfactory financial condition of the Association, having a cash balance of $2.433.39.

DR. R. L. GRINDLE, of Mt. Desert, reported ver-

[1] See page 133 of the Journal.

[2] See page 125 of the Journal.

bally the case of a patient who had three successive attacks of puerperal septicemia, successfully treated by the intra-uterine application of glycerine in suppositories.

DR. B. F. BRADBURY, of Norway, who was a brigade surgeon at Chickamauga, read a paper on

A DIVISION HOSPITAL AT CHICKAMAUGA.

DR. CHAS. D. SMITH, of Portland, read a paper on

TREATMENT OF CASES OF CHICKAMAUGA TYPHOID AT THE MAINE GENERAL HOSPITAL.

SURGEON BRADBURY'S paper called special attention to the efforts made by Surgeon-General Sternberg, by preliminary warning and instruction, to avert the epidemic which swept Camp Thomas. The story of overworked medical officers, insufficient supplies because of defective transportation, was the same already so many times repeated.

DR. O. DE S. DAVIES, of Augusta, read a paper on

NEURASTHENIA.

AFTERNOON SESSION.

DRS. F. W. ANTHONY, of Haverhill, and E. W. CUSHING, of Boston, were introduced as delegates from the Massachusetts Medical Society. Both gentlemen subsequently participated in the discussions and contributed not a little to their interest.

DR. F. W. LAMB, of Tilton, was introduced as a delegate from the New Hampshire Medical Society.

The President's Address upon matters of historical interest to the Association was delivered by DR. C. O. HUNT, of Portland. It reviewed medical work in Maine since the last meeting at Bangor in 1869.

By request of many members it was voted to instruct the Board of Censors to fix the date of the next meeting so as not to conflict with the date of the meeting of the American Medical Association.

DR. J. K. PHILLIPS, of Bangor, read a paper on

THIRTY APPENDECTOMIES,

and presented beautifully prepared specimens of appendices from all the cases with detailed histories.

In discussion, DR. ALFRED KING, of Portland, pointed out thirty-one conditions which have been mistaken in diagnosis for appendicitis, and urged early operation, especially in the doubtful cases.

DR. S. C. GORDON, of Portland, insisted upon treatment of the acute attack with salines, reserving operation for the interval, claiming that more than 90 per cent. of cases so treated recover from the first attack.

DR. GEORGE F. LIBBY reported a series of cases of middle-ear suppuration successfully treated by application of acetanilid.

EVENING SESSION.

DR. F. J. TAYLOR, of Pittsfield, read a paper on

THE THERAPEUTICS OF WHOOPING-COUGH,

laying stress on the advantages of vaporized formalin to allay the paroxysms.

In discussion it was brought out that in Maine, and especially Penobscot County, the mortality from whooping-cough was greater than that in measles or scarlatina.

DR. A. D. SAWYER, of Fort Fairfield, read a paper on

DISEASES OF THE UPPER AIR PASSAGES.

A series of seven-minute papers presented for discussion

LOBAR PNEUMONIA IN ITS CLINICAL VARIETIES, ITS SYMPTOMS, COURSE AND DURATION, ITS MEDICINAL TREATMENT AND ITS NON-MEDICINAL TREATMENT.

The discussion was postponed to listen to a paper read by invitation, from DR. E. W. CUSHING, of Boston, on

DISORDERS OF THE MENOPAUSE.

SECOND DAY. — MORNING SESSION.

The Association met at 9.45 o'clock, and adopted a standing rule providing for an annual dinner under the management of a committee appointed by the Association, individual members purchasing tickets and the Association bearing the cost of preparation and the entertainment of invited guests. Heretofore entertainment has always been at the expense of local members where the meetings were held.

DR. JAMES A. SPALDING, of Portland, read a paper on

SOME SEQUELÆ OF INFLUENZA, WITH SPECIAL REFERENCE TO THE EYE AND EAR.

The annual election of officers followed. Dr. B. T. Sanborn, of Augusta, superintendent of the Maine Insane Hospital, was the unanimous choice for President. Other officers are First Vice-President, Dr. B. F. Bradbury, Norway; Second Vice-President, Dr. W. L. Hunt, Bangor; Treasurer, Dr. Augustus S. Thayer, Portland; Recording Secretary, Dr. Charles D. Smith, Portland; Corresponding Secretary, Dr. A. D. Sawyer, Fort Fairfield.

Board of Censors: Drs. John F. Thompson, Portland; Arthur S. Gilson, Portland; Hiram Hunt, Greenville; John E. Walker, Thomaston; Gilbert M. Elliott, Brunswick.

Committee on Publication: Drs. Chas D. Smith, (*ex officio*), Portland; W. B. Moulton, Portland; E. J. McDonough, Portland; Geo. A. Coombs, Waldoboro; H. H. Purinton, Lewiston.

Business Committee: Drs. B. B. Foster, Portland; Stanley P. Warren, Portland.

The Secretary reported as deceased during the year, Drs. F. C. Hall, Lisbon Falls; Geo. Z. Higgins, Strong; J. M. Jonah, Eastport; H. C. Levensaler, Thomaston; C. J. Milliken, Cherryfield; A. P. Snow, Winthrop; D. D. Spear, Portland, and not previously reported, Dr. W. N. Adams, Brunswick.

DR. S. C. GORDON, of Portland, introduced the subject of the

ABUSE OF HOSPITAL CHARITY BY PEOPLE ABLE TO PAY,

and offered the following resolution:

Resolved, That charity work for people able to pay should cease in the institutions of this State.

Dr. Gordon said what was desired was an expression of the sentiment of the Association, which might be presented to the directors of the different hospitals.

In the discussion it was brought out as the sentiment of the Association that if some plan could be devised by the management of the hospitals whereby people able to pay could be required, in addition to the fixed charges for ward and nursing, to pay the same fees for medical and surgical work as they would at home, such fees in all cases to go to the treasury of

the institution and not to individual members of the staffs, the unequal competition on the part of the hospitals would be avoided or greatly lessened.

It was also apparent that the Association believed the plan for such an arrangement ought to be made by the institutions, and that the burden ought not to be laid on the profession.

The opinion was also expressed by Dr. C. O. Hunt, superintendent of the Maine General Hospital, that there were some difficulties in the way of arranging a scale of prices, to meet the different classes of paying patients. More than 90 per cent. of the patients who come under this class at the Maine General Hospital are from the small back towns, are of slender means and come with letters from their physicians asking for reductions in rates for their benefit. How should the standard be fixed? How was the superintendent to know whom to favor, and how was he to determine the ability of one person to pay more or less than another? He believed the principle of the resolution to be right, but did not think the remedy so easy as it seemed to many.

The resolution was given a unanimous passage. The Secretary was instructed to acquaint the presidents of other New England medical societies with this action.

Dr. S. C. Gordon, of Portland, read a paper on

CONSERVATIVE GYNECOLOGY,

based upon the ground that whatever conserved the health of the woman and cured her disease in the quickest and most complete way was the most conservative surgery. This he believed to be by complete instead of partial removal of the uterus and adnexa, for diseases of those organs.

Dr. S. H. Weeks, of Portland, read a paper advocating the

ABDOMINAL ROUTE IN PELVIC SURGERY OVER THE VAGINAL

in the greater proportion of cases in which the uterus or parts of the uterus and appendages are removed.

Dr. M. H. Richardson, in discussion, said carcinoma of the body or cervix was the one condition which made the vaginal route preferable, because one could draw away from the wound and the peritoneum a sloughing septic mass, instead of drawing it through and over it.

The evening session was held in City Hall at 8 o'clock. Reports were received from delegates to other medical societies and were referred by title to the Committee on Publication.

The Board of Censors made its final report as follows:

Bangor, Maine, June 8, 1899.

To the Officers and Members of the Maine Medical Association:

Gentlemen, — The Board of Censors desires to make its final report, embodying the following appointments and recommendations:

It is recommended that the next annual meeting of the Association be held in Portland, on Wednesday, Thursday and Friday, June 13, 14 and 15, 1900.

It is recommended that the selection of orator be left to the chairman of the next Board of Censors, with power.

The following appointments are made:

Visitors to the Maine Insane Hospital: Drs. O. C. S. Davies, Augusta; W. P. Giddings, Gardiner; W. B. Small, Lewiston.

Visitors to the Portland School for medical instruction: Drs. J. D. Cochrane, Saco; W. K. Oakes, Auburn.

Visitor to Medical School of Maine, (two years): Dr. J. M. Wakefield, Warren.

Delegates to American Medical Association: Drs. Alonzo Garcelon, Lewiston; S. C. Gordon, Portland; D. A. Robinson, Bangor.

New Hampshire: Drs. Chas. D. Smith, Portland; J. A. Randall, Old Orchard; F. L. Davis, Biddeford; A. Millett, Searsmont.

Vermont: Drs. W. D. Williamson, Gorham, N. H.; John D. Holt, Berlin, N. H.; D. H. Kelley, Mattawamkeag.

Massachusetts: Drs. J. K. Phillips, Bangor; Walter L. Hunt, Bangor; H. P. Merrill, Portland.

Rhode Island: Drs. R. L. Grindle, Mt. Desert; S. J. Bassford, Biddeford.

Connecticut: Drs. H. H. Smith, Whitneyville, Ct.; S. B. Hunter, Machias.

New York State Medical Association: Drs. Daniel McCann, Bangor; George A. Phillips, Ellsworth; Augustus S. Thayer, Portland.

New Brunswick: Drs. Charles E. Williams, Houlton; A. D. Sawyer, Fort Fairfield.

Maritime Medical Association: Drs. D. B. Myshrall, Portland; Stephen E. Webber, Calais.

Delegates to the Pharmaceutical Convention, 1900: Drs. C. O. Hunt, Portland; A. Mitchell, Brunswick; Ad. S. Thayer, Portland.

Committee to arrange for entertainment at next annual meeting: Drs. H. H. Brock, Portland; J. W. Bowers, Portland; John F. Thompson, Portland.

It is recommended that the President and Secretary have power to grant credentials to members wishing to attend the meeting of the American Medical Association as delegates, and to fill vacancies occurring in delegations to other State societies.

Also, that the appointment of delegates to county societies be left to the President and Secretary, with power.

It is also recommended that applications for membership received this year for the first time and not acted upon be referred to the next Board of Censors.

The report was accepted and its recommendations adopted.

Dr. Maurice H. Richardson, of Boston, then delivered the annual oration upon the subject of

ACUTE ABDOMINAL SYMPTOMS REQUIRING IMMEDIATE SURGICAL INTERVENTION.

The thanks of the Association were extended to the orator for his valuable address, and a copy requested for publication.

After the usual votes of thanks to retiring officers, the local committee and the city of Bangor, the thanks of the Association were extended to the Penobscot County Medical Society, which, through its members residing in Bangor, had entertained the Association during its stay.

The Association then adjourned to the second Wednesday in June, 1900.

Dr. D. A. Robinson, on behalf of the Penobscot County Medical Society, extended to the Association an invitation to remain and partake of a collation which had been prepared in the hall.

It had been the intent of the committee to have entertained the Association at the Niben Club a few miles out of town, after the session of the afternoon, but rain had necessitated the abandonment of this plan.

The meeting was one of the best for many years, both in the character of the papers and the attendance, which was exceptionally large.

During the session the censors recommended and the Association elected thirty-one new members.

The next meeting will be held in Portland in 1900, on the second Wednesday, Thursday and Friday in June.

AMERICAN ORTHOPEDIC ASSOCIATION.

THIRTEENTH ANNUAL MEETING, HELD IN NEW YORK, MAY 31, JUNE 1 AND 2, 1899.

FIRST DAY.

DR. W. R. TOWNSEND, of New York, delivered the

PRESIDENT'S ADDRESS.

He described the development of orthopedic surgery, as indicated by hospitals and dispensaries for such work, in and about New York City. He said that the pioneer institution had been established in 1866, largely through the efforts of the late Dr. C. Fayette Taylor. This subsequently moved to the present site of the New York Orthopedic Dispensary and Hospital. In 1870 the Hospital for Ruptured and Crippled had been ready for occupancy. Its founder, the well-known and indefatigable worker in this field, Dr. James Knight, died in 1887, after many years of unremitting labor for his chosen specialty. The present institution had been recently supplied with the most modern operating equipment, together with pathological and bacteriological laboratories. Altogether there were more than five hundred beds for orthopedic patients in New York City, and during last year about fifteen thousand out-patients were treated.

DR. CHARLES FAYETTE TAYLOR.

DR. E. H. BRADFORD, of Boston, presented a memorial address on the life and labors of this eminent orthopedic surgeon.

THE FORCIBLE CORRECTION OF LATERAL CURVATURE.

DRS. E. H. BRADFORD and E. G. BRACKETT, of Boston, presented this communication.

These authors asserted that it was particularly desirable in these cases to make the pressure over three points, namely, (1) Over the point of maximum curvature; (2) over the pelvis; and (3) on the neck or above the scapulæ, using of course, counterpressure at three corresponding positions anteriorly. The treatment was carried out with the aid of the hammock, or preferably the Brackett frame — a mechanical device for making the requisite pressure in the regions mentioned. Not only did this treatment reduce the deformity, but it often increased the flexibility. It was applicable to cases in which other methods could not be used, and to cases in the growing stage in which there was more or less bony change.

SOME REMARKS ON THE CLASS METHOD OF GYMNASTIC TREATMENT IN LATERAL CURVATURE.

DR. WALTER TRUSLOW, of New York, presented this paper by invitation, and subsequently gave an interesting exhibition of the method at the Hospital for Ruptured and Crippled. The paper was based on his work in this field during the past seventeen months on 199 cases, varying in age from eleven to sixteen years, with a few exceptions. A little less than fifty per cent. of the cases had presented postural deformities, while the other half had had more or less fixed deformities beyond the control of the motor apparatus. The treatment had aimed to so train the muscles as to allow of their assuming an approximately normal position. Experience had demonstrated the advisability of dividing the cases into three classes, namely: (1) Children just past puberty beginning the treatment; (2) children who still required treatment but were sufficiently advanced to work with older ones just beginning; and (3) those who had acquired sufficient muscular development to engage in heavier work. The method was an adaptation of the Swedish educational gymnastic movements. These exercises had been found well adapted to the isolation and stimulation into activity of groups of muscles, thus securing correction of faulty positions and at the same time developing purposeful and intelligent co-operation. Nearly all those who had faithfully followed the treatment had exhibited decided improvement.

SOME POST-PARALYTIC DEFORMITIES AND THEIR TREATMENT.

DR. JACOB TESCHNER, of New York, presented this paper. He said that he looked upon the reaction of degeneration in the muscle as evidence only that the greater part of the muscle had been changed, and did not necessarily mean that there were no fasiculi that retained their normal properties. In a comparatively short time he had secured in each case treated far better results than had been secured by others from a much longer use of massage and electricity.

DR. J. E. GOLDTHWAIT, of Boston, in opening the discussion on the foregoing papers, said that it was well to remember that forcible correction did not cure rotary lateral curvature, though it was a valuable adjunct to other measures. According to his experience the maximum improvement had been attained by the forcible method in a short time. It was important to study the record of the pulse taken before exercising and ten minutes afterward, as this constituted an important factor in prescribing the kind and amount of exercise best suited to the individual patient. The exercise should be so regulated that the pulse-rate would be lower after than before exercise.

DR. JOHN RIDLON, of Chicago, said that in dispensary work he had obtained some excellent results by applying plaster jackets to patients while lying on a modification of Goldthwait's frame.

DR. H. AUGUSTUS WILSON, of Philadelphia, spoke in favor of manipulations carried out with the surgeon's knee as a fulcrum, and claimed that not only were the results good, but the patient was spared the terrifying effect of seeing the large and complicated mechanical devices. The patient being seated on a chair with the pelvis fixed, the back to the manipulator and the hands raised, the surgeon bent the patient laterally over his knee, and after the full amount of flexion had been obtained by rotation of the shoulders in one or the other direction, it was possible to obtain an untwisting that was exceedingly valuable in promoting flexibility of the spine and in aiding the development of the muscles.

DR. LOUIS A. WEIGEL, of Rochester, pointed out

the fact that Dr. Brackett recommended a method of correction that was maintained for a considerable time — a point of no little importance.

Dr. B. E. McKenzie, of Toronto, said that he had already published a method of correction in which the patient while suspended by the neck had lateral traction made at the point of greatest lateral curvature, while the surgeon used his hands to untwist the rotation. He favored a combination of individual and class instruction. The latter had the very distinct advantage of stimulating rivalry among the pupils.

Dr. T. E. Satterthwaite, of New York, spoke in favor of class work and of manual, as opposed to force exerted by machines.

Dr. Reginald H. Sayre, of New York, said that the patient could not voluntarily correct the deformity until adhesions had been broken up, and in a certain number of cases in which it had seemed impossible to do much by the ordinary means he had given an anesthetic and by violent manipulation had broken up the adhesions. While still recumbent, strong traction had been made and a plaster jacket applied. This treatment had been followed by little or no reaction, and in some of the cases the result had been quite good. It was essential that the patient should understand the object of the treatment so that he could co-operate with the surgeon and carry out the principles during the greater part of each twenty-four hours.

Dr. W. E. Wirt, of Cleveland, thought if more than four or five were in a class the details would be neglected. His own plan was to correct the deformity as far as possible by suspension and posture; prepare a plaster-of-Paris mould from the patient, and so alter it that the corset modelled on this mould would be somewhat over-corrected. At night the corset was replaced by a sleeping apparatus.

Dr. R. Tunstall Taylor, of Baltimore, said that where the patient was too weak or too listless to hold the body straight he used a brace, modelled after the human hand, and having the pelvis for its base of support. Exercising before the looking-glass and reference to photographs were aids to both patient and surgeon.

CONGENITAL DEFORMITIES OF THE SPINE.

Dr. Augustus Thorndike, of Boston, read a paper on this subject, illustrating it freely with anatomical and pathological plates. Speaking of spina bifida, he said that a very large proportion of these cases died within the first year of life. At present the tendency was to favor excision. Excision should be done whenever rupture had occurred or was imminent. Excision purely for the purpose of relieving paralysis was rarely successful.

THE DIAGNOSTIC VALUE OF RADIOGRAPHY IN ORTHOPEDIC AND GENERAL SURGERY.

Dr. L. A. Weigel, of Rochester, made some remarks on this subject, illustrating them with a large number of lantern slides. He did not believe that the x-rays led to such fallacious results as many claimed, but the radiograph, to be of value, must be sufficiently good to show the structure of bone, and must be free from distortion. He had been using the x-rays for two years and a half, employing for one year a coil machine, and for the remainder of that time the static machine, which he greatly preferred. In not a single instance had he produced anything even approximating an x-ray burn. This, he was sure, was solely due to the avoidance of excessively long exposures, and to operating with the vacuum tube always at least eight inches from the subject, and usually at a distance of eighteen inches. At this distance an adult foot would require an exposure of about three minutes, and that of a child about forty seconds. For the hand one minute would suffice, while for the elbow and knee the exposure should be five or six minutes.

SUBCUTANEOUS TENOTOMY: BIOGRAPHICAL NOTES.

Dr. A. B. Judson, of New York, in this brief sketch, told of the early work of Stromeyer, W. J. Little and William Detmold.

REPORT OF THE COMMITTEE ON RECORDING LATERAL CURVATURE.

This report had been previously circulated among the members. The conclusion arrived at by the committee after much experimentation and study was, that although photography presented many defects it was the best method at present known for recording cases of lateral curvature.

Dr. McKenzie, in opening the discussion on the report, remarked that he had gradually discarded every other method in favor of "honest photography."

Dr. H. A. Wilson thought nothing else could compare with honest photography, not only because of the accuracy of the record, but because the personal equation was reduced to the minimum and the results admitted of ready interpretation.

Dr. N. M. Shaffer and Dr. Lovett both advocated photography, the latter adding that in recording muscular conditions the record should state under what conditions the standing record had been made.

Dr. Henry Ling Taylor, of New York, recommended that the standing and sitting height of the patient should be recorded under the same conditions at intervals of about three months. As to the trustworthiness of the results obtained by photography, every practical photographer knew well that without any intention to deceive many inaccuracies might be introduced.

Drs. Truslow, Dane and C. E. Young described simple and ready methods of making clinical records of these cases.

After a full discussion of the report, the Association decided that it was inexpedient at present to indorse any one method of making records of cases of lateral curvature.

PIGEON TOE.

Dr. W. Burton Hopkins, of Philadelphia, presented, by invitation, a paper on this subject, in which he described his ingenious swivel and spring device for correcting pigeon toe. The arrangement could be readily imbedded in the heel of the shoe, and as now made did not easily get out of order. Its action was to throw the foot out as the person walked.

Dr. L. W. Hubbard, of New York, said that most of his cases of pigeon toe had been in young children who did not wear high heels on their shoes, and that, therefore, there was no place for the attachment of this device.

Dr. Whitman thought these cases were almost always symptomatic of weak feet, and this gave clue to the rational treatment.

Dr. Ridlon remarked that most of his cases had been associated with equinovarus.

DR. C. C. FOSTER, of Cambridge, had found that a cure could be effected by military drill, and appealing to personal vanity.

DR. H. A. WILSON said that it had been demonstrated that the action of this device was the production of ankle-joint rotation.

SECOND DAY.

A STUDY OF POTT'S PARAPLEGIA AS AFFECTED BY CORRECTION OF THE SPINAL DEFORMITY.

DR. JOEL E. GOLDTHWAIT, of Boston, presented a communication on this subject, based on the observation of 11 cases, three of them being between four and six years old. In one of the adults, a girl of twenty, the paraplegia had been almost magically relieved in a few hours by the application of the jacket, but the paraplegia had returned when the jacket had become soft.

DR. V. P. GIBNEY, of New York, referred to the case of a man upon whom Dr. Abbe had performed laminectomy, and had removed from the spinal canal a mass of granulomatous material, with the result that the cord had immediately begun to pulsate again, and its color had been improved. The man had steadily improved since the operation, and was able to sit up, although he had not yet essayed to walk.

DR. SHERMAN was inclined to suspect that in the case in which there had been such sudden and wonderful improvement in the paralysis there was a hysterical element.

DR. R. W. LOVETT, of Boston, said that it was now quite generally admitted that the pressure symptoms were due to a lymphatic edema, and if this view were correct, it might explain the sudden change observed by Dr. Goldthwait.

DR. WEIGEL cited a case illustrating the fact that although the external deformity and the paralysis were both slight, there might be such extensive destruction of the vertebræ as to render forcible correction an exceedingly hazardous procedure.

DR. GOLDTHWAIT, in closing, said that in none of his cases had there been a permanent recession of the deformity, although all had been relieved. He did not believe the case exhibiting the sudden changes in the paralysis was hysterical; he had seen the same thing in several young men.

OSTEO-ARTHRITIS OF THE SPINE: SPONDYLITIS DEFORMANS.[1]

Dr. Goldthwait also presented this paper, which contained the histories of thirty-five cases. He stated that the disease belonged to adult life, but the etiology was obscure. The disease consisted in the formation of nodules on the edge of the articular cartilages, with a subsequent ossification of these nodes, and an extension of the process into the adjacent ligaments. It usually began anteriorly and to one side. As anchylosis proceeded, pain was complained of, and the thorax became rigid. The paralysis was always partially, but never completely, recovered from. The treatment, both medicinal and hygienic, should be stimulating. Hot baths, if of short duration, were useful, but if prolonged, they caused prostration and made the patient worse.

DR. RIDLON described a case occurring in a woman of twenty-five in which, although the disease was quite advanced, he had succeeded in relieving her far beyond his expectations, by placing her under an anesthetic and subjecting the parts to violent manipulation. She now had in the lower portion of the spine about half the normal range of motion, and her chest expansion had returned almost to the normal for a woman.

DR. C. L. STARR, of Toronto, reported an interesting case in which a man of forty years, although suffering from the disease in such an advanced stage that the ribs had become anchylosed, was able to pursue his occupation as a clarionet player in a band.

OPERATIVE TREATMENT OF CONGENITAL LUXATION OF THE HIP.

DR. G. G. DAVIS, of Philadelphia, described his method of making a new acetabulum in these cases by the use of a wood-carver's gouge and an instrument known as a "rose burr."

A CASE OF DORSAL DISLOCATION OF THE HIP OCCURRING SPONTANEOUSLY DURING THE COURSE OF AN ACUTE OSTEOMYELITIS OF THE NECK AND SHAFT OF THE FEMUR.

DR. W. H. TAYLOR, of Philadelphia, reported this case. The patient, a boy of thirteen, had been injured, apparently only slightly, while playing football, but after a short time he had begun to get worse instead of better. A few weeks later, examination under an anesthetic showed that, as a result of an extensive osteomyelitis, a true spontaneous dislocation had occurred. The exact time of the occurrence of the dislocation was not known. It was not impossible that if the distention of the capsule prior to this accident had been recognized and relieved, the dislocation might have been prevented.

REDUCTION OF CONGENITAL HIP DISLOCATION BY THE LORENZ METHOD.

DR. W. E. WIRT, of Cleveland, reported two cases treated by the bloodless method. The first one had done well, but during his absence as naval surgeon during the late war, the child had fallen into the hands of a surgeon in Cincinnati who had insisted that the joint was perfect and that there was no further need for protective apparatus. In about six days the dislocation had returned. On his return home Dr. Wirt had operated again, with good result.

CONGENITAL DISLOCATION OF THE HIP.

DR. HARRY M. SHERMAN, of San Francisco, read a paper on this subject. He had done the bloody operation on nine hips. In three of these the luxation had relapsed after it had been supposed that there was permanent anchylosis; in two or three good motion had been secured; in the others the reductions had been stable, but anchylosis had occurred. He was inclined to attribute this anchylosis to granulation tissue springing up from the exposed cancellous tissue and encircling the head of the bone. He had subjected thirteen joints to treatment by the bloodless method of Lorenz, with varying results. In seven the luxation had returned. He preferred now to satisfy himself by incision and digital exploration that the head of the bone had been certainly placed in the acetabulum. He proposed to try to *punch* out an acetabulum in an upward and inward direction, thus securing sufficient depth without exposing so much cancellous tissue.

(To be continued.)

Recent Literature.

Hand-book of Materia Medica for Trained Nurses. Including Sections on Therapeutics and Toxicology and a Glossary of Terms, with Dose and Use of Each Drug. By John E. Goff, Ph.G., Apothecary in the Rhode Island Hospital, Providence. Philadelphia: P. Blakiston, Son & Co. 1898.

This is a compactly arranged and clearly written book of 235 pages. The writer's experience as a pharmacist has enabled him to give most useful rules for the handling of drugs and he has taken pains to emphasize those points which are most desirable for a nurse to know. The first section is devoted to officinal drugs and preparations, and the second section relates to the chemistry of the subject. Short chapters on therapeutics and toxicology and a glossary of 65 pages complete the volume. Questions at the close of each chapter help the reader to fix the most important facts.

The work is most satisfactory as far as it goes, but it seems unfortunate not to combine more therapeutics with the materia medica. To nurses as well as doctors materia medica of itself offers little attraction, because their interest lies in its application. A book, therefore, which combines the two subjects will appeal to them more strongly and in the limited time at their disposal will be more suited to their requirements.

Lessons in Hypnotism and the Use of Suggestion, based upon the Neuron Motility Hypothesis. By Leslie J. Meacham. Pp. ix; 192. Cincinnati, O.: The Bishop Publishing Co.

This is the second edition of this book. In the preface the author states that adverse criticisms of the earlier have been few and slight. Our suspicion is that this may have been due to a somewhat uncritical attitude on the part of reviewers, rather than to the excellence of the book. In the first place, the author unequivocally gives himself over to the neuron motility hypothesis, which he erroneously states was first presented by F. X. Dercum, of Philadelphia. Having accepted the theory the author finds many subtle problems answered. For example, he writes, p. 39, "The process movement theory, however, renders psychological problems that hitherto have seemed inexplainable as demonstrable as the simplest proposition of Euclid," and again, p. 45, "An act of perception, therefore, consists of changes in the relation of cortical neurons with one another, these changes corresponding to and depending upon certain physical impacts upon the sensory organs." Sleep is disposed of as "a condition of neuron plasticity."

Such statements as these do not lead us to look with over-much confidence on the theoretic chapters of the book. On its practical side the book may hardly be called original, but this portion is a vast improvement on the "Theory." There are many suggestions which, no doubt, would be of value in practice.

The book is embellished with a number of reproductions of photographs illustrative of methods of hypnosis. The author is evidently much interested and well informed on the subject of which he writes, and on the whole, brings to bear in its treatment a scientific spirit, if not scientific exactness.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 10, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

A CRITICISM OF THE PROPOSED CHANGE IN THE CURRICULUM OF THE HARVARD MEDICAL SCHOOL.

In our editorial communication of June 8th we spoke of the proposed new curriculum at the Harvard Medical School. The essential feature of the change is, in the first place, concentration on one main subject of study, and in the second place, as a natural consequence, a more logical sequence of the fundamental branches, such as anatomy, physiology and patholgy, thereby conducing to greater ease both of teaching and learning.

That such a plan, somewhat radical in character, should escape criticism, is neither likely nor desirable. As we previously urged, experience alone can ultimately determine the wisdom and effectiveness of the suggested scheme. In the meantime candid criticism and an expression of other points of view must be welcomed. Such a criticism has recently appeared in the *British Medical Journal* of July 22d, under the heading, "The New Medical Curriculum at Harvard." The writer expresses interest in the new departure, but on the whole regards it as a somewhat retrograde movement. After quoting the outlined plan, as detailed in our editorial already referred to, he continues as follows: "While we have no wish to prejudge the subject, it seems to us impossible to believe that anatomy and physiology can each be learnt in four months. The mere dissection of the body would, we should have thought, be impossible in the time, and anatomy cannot be learnt — at least as we learn it here — without much reading, nor remembered without repeated observation. We cannot but wonder how much anatomy the student, who has not thought of it for a year and a half previously, will command when he goes into the wards. We have often urged that for the proper study of anatomy and physiology it is desirable that nothing else should be studied during the first year and a half, and here is a proposal that the whole of these vast subjects should be finished in two periods of four months each. There

will be no means of testing or comparing the results, for the examinations must of necessity adapt themselves to the new level, and the abiding knowledge to be employed in practice, which is the thing of real importance, can hardly be tested at all. Even though a student be able to pass fairly at the end of January, when it appears the examination in anatomy will be held, it is most unlikely that learning so hastily crammed can be properly assimilated, or form a sound and permanent acquirement."

Several of these statements are worthy of comment. To begin with, we quite agree with the *British Medical Journal* that anatomy and physiology cannot be learned in four months, or, indeed, in as many years. It is, in fact, a mistake to speak of such progressive sciences as ever being learned; our knowledge of them, notably of physiology, must always be relative. The argument of the advocates of the new scheme simply is that the essential rudiments of these sciences may be better taught and learned in four months of concentrated effort than in a year or more of unconcentrated study, and not only that, but that actually more hours may be gained by the new method than was possible as the subjects were before taught, at least at the Harvard School. Just why a student should be more likely to forget his anatomy or physiology, conscientiously studied for four months, than if studied for a year or more, in a less thorough manner, it is hard to see. The value of such study must lie rather in methods used and in the trend given the student's mind than in a mere collection of facts, to which unfortunately such sciences are too often degraded. With the enormous growth of detail, which the last few years has witnessed, it is evident that the elementary student should only be called upon to master principles. These he will always need, and facts, merely as facts, may well be relegated to a subordinate place in his mind. We cannot, therefore, regard the argument of our contemporary as in any way valid, when it wonders "how much anatomy the student, who has not thought of it for a year and a half previously, will command when he goes into the wards." If he has been properly taught, the student should always be able to command what he needs at a given time, just as the practitioner does, and concentration of attention can in no way diminish this possibility, so far as we can see. Nor do we think that "learning so hastily crammed cannot be properly assimilated." Again, if proper methods of study are inculcated, the facts will take care of themselves.

The error of all such arguments seems to us to lie in the failure to appreciate that the essence of preliminary medical education, as of all other education, lies in its capacity to train the mind to future accomplishment, rather than to make it merely a storehouse of facts. As Charles Sedgewick Minot puts it, "We must teach how to learn." It is probable that the new plan of concentration and gradation will tend to bring this end to pass; if so, it will have accomplished its main purpose. As we have before stated, the detailed working-out of the scheme must be left to experience. If it ultimately fails, we feel confident it will not be for the reasons adduced by the *British Medical Journal*.

SANITATION IN PORTO RICO.

ONE of the most gratifying results of the American occupation of Cuba and Porto Rico has certainly been the activity of the medical branch of the service. That such activity was most urgently needed has been sufficiently apparent from the moment the real conditions were brought into public view. That it has been marvellously efficacious has been equally apparent, as the one instance of General Wood's successful encounter with yellow fever at Santiago amply demonstrates.

Most excellent work has also been done at Porto Rico toward the establishment of definite sanitary regulations. We are in receipt of a circular dated at San Juan, July 18th, which sets forth in detail the duties of the Superior Board of Health for the island. The functions of the Board are to be not only of a supervising character as regards general matters of health, but an especial attempt is to be made to study vital statistics, investigate causes of disease, including those of domestic animals, to disseminate information among the people, and to institute sanitary inspections of public institutions and places. The Board will also assume responsibility for regulations governing the practice of medicine, surgery, pharmacy and allied branches, and investigate the violation of laws governing the purity of foods, drinks, drugs and medicines. The document leaves nothing unconsidered in relation to public hygiene and if it can be carried out in detail will undoubtedly do much toward establishing a high degree of general health. Such energetic work is worthy of the highest praise, and shows what may be done under proper management.

Chief-Surgeon John Van R. Hoff, of the Department of Porto Rico, writes: "We commenced our sanitary part of the white man's burden by vaccinating 180,000 of the inhabitants and manufacturing the virus to do it."

MEDICAL NOTES.

LANE MEDICAL LECTURES. — Michael Foster, of London, will deliver the next course at Cooper Medical College, San Francisco, in 1900.

A FUND FOR BACTERIOLOGICAL RESEARCH. — Efforts are being made in France to secure by public subscription a fund for bacteriological research; 78,500 francs has already been subscribed.

APPOINTMENT OF DR. THOMAS S. K. MORTON. — Dr. Thomas S. K. Morton has been elected professor of the principles and practice of surgery in the Woman's Medical College of Pennsylvania, in succession to Dr John B. Roberts, resigned.

A STATUE OF BARON LARREY. — A bronze statue of Baron Larrey, the celebrated surgeon-in-chief of the army of Napoleon the First, was dedicated on June 8th at the Military Hospital at Val-de-Grace.

COMPULSORY VACCINATION. — The Japanese Government has decreed compulsory vaccination throughout the kingdom. We assume that the local Pooh-Bah will take care of the Japanese conscientious objector. — *Medical Press and Circular.*

OSTEOPATHY DECLARED UNLAWFUL IN PENNSYLVANIA. — We learn from the *Medical Record* that the Medical Council of the State of Pennsylvania decided on May 24th, that the practice of osteopathy within the State is illegal, and that those therein engaged are amenable to the law.

THE SPREAD OF CONTAGIOUS DISEASES. — We learn from the *Medical Record* that the Pennsylvania State Board of Health has adopted a regulation requiring teachers in school whose boards act also as boards of health to report immediately to the secretaries of such boards or to the agents designated by them all cases of contagious diseases occurring in their respective schools.

WHAT THE HUMAN BODY WILL YIELD. — A French statistician has calculated that the average human body contains enough fat to produce 13 pounds of candles; enough carbon to make 65 gross of "lead" pencils; and sufficient phosphorus to tip 820,000 matches. Perhaps he will complete his observations by calculating how many bone-handled knives one body would furnish, how many watch-springs could be made from the iron in the blood, and how much mortar could be made from the lime contained in the tissues. When he has done this we will suggest sundry other as yet unsolved problems. — *Medical Press and Circular.*

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 9, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 53, scarlet fever 16, measles 14, typhoid fever 17, small pox 1.

LEAD-POISONING FROM DRIVEN-WELL WATER. — The State Board of Health has recently held a public hearing at Lowell, Mass., regarding lead poisoning from driven-well water. It appears from the report that in every one of seventy-four samples of water examined a dangerous amount of lead was found. Physicians in Lowell have recently reported forty cases of poisoning of varying degrees of severity coming under their observation. The removal of lead pipes in houses through which water is obtained for drinking or cooking purposes was urged. It was further stated that a filter, similar to one now in use in Lawrence, might be built as a protection to public health.

TWO CENTENARIANS. — Mrs. Phœbe W. Crabbee, of Norwalk, Conn., has recently celebrated her one hundred and second birthday. She was the second of a family of seven children, only one of whom has died under eighty, and then through an accident. Mrs. Sally Batchelder, of Peabody, celebrated her one hundred and fifth birthday on August 8th. She is reported to have recovered from a fracture of the lower extremity which she sustained in her one hundredth year.

SANITATION OF PICNIC GROUNDS. — The State Board of Health is about to undertake an examination of picnic grounds and certain summer resorts relative to their sanitary condition. Special notice will be taken of water supply at different places where persons in large numbers habitually congregate, and sewerage systems will also receive careful consideration. It has been observed that typhoid fever is very prevalent in September and October, a fact which it is thought may be attributed directly or indirectly to the lack of proper sanitary arrangements in crowded summer resorts.

A REMARKABLE RECORD. — Helen Keller, who is handicapped by the loss of the senses of sight, hearing and the consequent inability to speak, has passed her examinations for entrance to Radcliffe College. This is, no doubt, the most remarkable example on record of the cultivation of the mind almost entirely through the sense of touch.

NEW YORK.

PROPOSED LEGISLATION REGARDING CHRISTIAN SCIENCE. — It is announced that the President of the Legal and Medical Relief Society, Mr. Sutro, has appointed the following committee (to which his own name has been added) in the matter of proposed legislation relating to Christian Science: S. B. Livingston, President of the Society of Medical Jurisprudence; Walter S. Logan, President of the New York State Bar Association; Alderman Howard P. Okie; Reynold W. Wilcox, M.D., President of St. Mark's Hospital; George F. Shrady, M.D.; Edward Lauterbach; John Sabine Smith; Thaddeus D. Kenneson, and A. Ernest Gallant, M.D. They will draft a bill for presentation in the Legislature which it is hoped will be of practical service in placing Christian Science healers and others undertaking to cure disease without visible agencies under the same legal restraints as ordinary practitioners of medicine.

ORDINANCE FOR REGULATION OF SURFACE CARS. — On Sunday, July 30th, two persons were killed by the trolley cars in Brooklyn and one in the Borough of the Bronx. This swells the list of fatalities from electric cars in the former borough to 248, and in view of the accidents that are constantly occurring in all parts of the city, an ordinance has been introduced in the Municipal Council providing for the regulation of the speed of surface cars and the compelling of such cars to stop on signal. Another section of the ordinance provides for the appointment of a commission, consisting of one electrician, one physician and one experienced employee of a surface railway, to act as a

board of examiners, from whom it shall be required that all applicants for positions on surface lines must receive certificates, both as to their physical condition and "professional" ability, in order to render them eligible for a license.

A Case of Ptomaine Poisoning. — The Hon. Carl Schurz recently had a very narrow escape from death by ptomaine poisoning, in which the attack closely resembled that which proved fatal in the case of Anton Seidl, the lamented musical authority. It is believed to have been due to some fish which he ate during a trip to New York from his summer home at Lake George. By great good fortune Dr. A. Jacobi happened to be with him at the time, and the prompt treatment which he instituted was no doubt the means of saving the distinguished patient's life.

Forestry Department, Cornell University. — Cornell University, which boasts the distinction of being the only institution of learning in the country which has a forestry department, having secured 30,000 acres of woodland in the Adirondack Mountains, near Axton, N. Y., Professors Gifford and Roth have recently been visiting the tract, inspecting the property and directing the work of the surveyors. The students in forestry, it is announced, will receive instruction in the theory of the subject from October until April, and from that time until commencement study its practical side in the Adirondacks.

Typhoid Fever at Flushing. — An examination of the drinking water supplied to the village of Flushing, in which there has been an outbreak of typhoid fever, has shown that the water is probably not responsible for the disease, and it is now suspected that the typhoid is due to polluted milk. One of the local physicians, it is said, has made the discovery that some of the cases in the hospital and ten outside belonged to families which were supplied by one milkman, and the facts have been reported to the Board of Health for investigation.

A Possible Epidemic of Poliomyelitis. — An epidemic of very unusual character has been in progress for some time among the young children in Poughkeepsie. The disease, which at the outset is characterized by considerable febrile action, is apparently infantile spinal paralysis, and if it be true, as has been stated, that in no instance has there been more than one case in a single family, its infectiousness would seem to be somewhat problematical. The physicians of the place have been naturally a good deal puzzled by the outbreak, and, on the invitation of Dr. D. B. Sheedy, Dr. Henry D. Chapin, professor of children's diseases in the New York Post Graduate Medical School, has been making an investigation of the disease. The fact that no deaths have been reported, as well as the general character of the symptoms noted, would go to show that the trouble is certainly not cerebro-spinal fever. The newspapers report that there have been as many as 150 cases, though this is probably a considerable exaggeration, and it is now stated that the disease has already made its appearance in New York. Whether this is really the case appears to be uncertain, as infantile paralysis is not classed among the affections calling for a report to the Bureau of Contagious Diseases, but Dr. Tracy, the Registrar of Records of the Health Department, is authority for the statement that no epidemic of this disease has ever been reported in this city.

A Bequest to a School for Feeble-Minded. — By the will of the late Benjamin D. Maxham, of Vineland, N. J., a legacy of $100,000, to be paid on the death of his wife, is left to the New Jersey Training School for Feeble-Minded Children, of which he was one of the founders and directors.

A Statement by Health Officer Doty on Yellow Fever. — On the occasion of the discharge from the hospital on Swinburne Island of Oscar F. Lackey, the first patient treated with his new yellow-fever antitoxin, Health Officer Doty has made a public statement in regard to the case. After stating that three subcutaneous injections of the serum, two of twenty-five cubic centimetres and one of fifty centimetres, were made, and that no other treatment was employed, he goes on to say: "From a scientific point of view, one case cannot prove the value or worthlessness of the serum. Therefore, I regard it as premature to give an opinion on this subject until a sufficient number of cases has been similarly treated, and enough evidence presented to justify it. . . . I desire to repeat the statement already made, that this department claims no discovery, either as to the isolation of the specific organism or in the production of the serum. The object of the investigation at the quarantine laboratory, which has been carried on for the last two years, is to test the value of the claim made by Professor Sanarelli, of Montevideo, that he has discovered the germ of yellow fever and has prevented and cured the disease in the human being by the use of the serum. The importance of this subject, particularly to the people of the United States, cannot be overestimated."

Miscellany.

THE CARE OF LEPROSY IN ECUADOR.

In a recent report by the United States Minister to Ecuador considerable space is given to the subject of leprosy as existing in that republic, and a monograph on this disease by Dr. Rivadeinera, in charge of the Quito Leper Asylum, is also transmitted.

According to Dr. Rivadeinera, all the lepers of the republic are segregated in the leper hospitals at Quito and Cuenca. In the former, a city of 80,000 inhabitants, there are 37 male and 40 female lepers; in the latter, a town of 30,000 inhabitants, there are 30 males and 35 females afflicted with leprosy. The climatic and local conditions of Quito do not appear to be as favorable for the spread of leprosy as in Cuenca, most of the lepers treated in the former place being brought from Ambato. The leper asylum at Quito is

supported by public charity and is only one branch of a general eleemosynary institution caring for paupers, orphans, inebriates, the insane, and other defective classes. Dr. Rivadienera has been connected with the leper hospital since 1886. He finds that the tuberculous form is much the most frequent in Ecuador, and states that at present no case of mutilating leprosy exists in that country. He observes that the disease usually develops about puberty, but states positively that some cases are congenital. He believes that heredity and contagion are the chief causes in the propagation of leprosy, and says that he has seen many cases which seemingly developed from contagion and inoculation. Dr. Rivadeinera is convinced that syphilis and leprosy are antagonistic and is positive that the latter disease can be cured if taken in the early stages. He states that in the thirteen years he has been treating leprosy in Quito fourteen patients have been discharged from the asylum as cured, "so pronounced by a board of physicians," and that two more patients are nearly ready to be discharged as cured. His treatment, he says, varies with the length of time the disease has existed, the form it has assumed and, above all, with its complications. Among the remedies successfully employed he mentions chaulmoogra. resorcin, carbolic acid and arsenical compounds, usually combined with vegetable tonics.

PLAGUE IN MONKEYS AND SQUIRRELS.

WE learn through the *Journal of Tropical Medicine* that interesting and important investigations have been made by Drs. Alice M. Cothoru and C. J. R. Milne regarding the susceptibility of certain of the lower animals to plague in India. It had been observed that several monkeys had dropped dead from trees, two of which were carefully examined.

In the first there was a bubo the size of a large cherry in the left groin, which on dissection consisted of a group of four glands, hard and purplish in color, with a good deal of edema of the surrounding tissue. From this a smear preparation was made, which showed an enormous number of organisms resembling the plague bacillus; inoculation of a tube of agar showed within twenty-four hours plague-like colonies. The spleen was much enlarged, and microscopical and culture preparations were made with the same result as from the bubo.

In the second monkey there was a small bubo about the size of a bean, with some fulness in the right axilla. The spleen resembled that in the first monkey, and gave both a good smear preparation and a growth of plague-like colonies within twenty-four hours.

In both monkeys the general appearance was similar to that observed in human subjects dead from plague. There were numerous subserous and submucous ecchymoses and the blood was dark and unduly fluid.

On December 17th the body of a gray striped squirrel was examined. There was no bubo, but the spleen was nearly three inches long, about one inch wide and three-quarters of an inch deep. A smear preparation from it showed typical bacilli in large quantities.

The importance of the fact that animals such as monkeys and squirrels are also susceptible to natural plague infection, in addition to rats, cannot be overestimated, especially in their relation to the carrying of infection from one district village to another. These squirrels and monkeys are so common in India that they might well be considered as pests.

THE HANDWRITING OF DOCTORS.

AMONG the many things that Napoleon has to answer for is the popular notion that an illegible handwriting is a mark of intellectual superiority. How far this may serve to explain the fortuitous concourse of scratches, dashes and blots which is too often handed to anxious sufferers as a prescription by medical oracles we are not prepared to say, but the fact is notorious that the writing of many doctors is of such a character that, like paleographic scripts, it can be read only by adepts. We have seen prescriptions which could be interpreted only by those who had undergone a special initiation. This obscurity may, of course, have its advantages from certain points of view, but there is always the risk that the adept may not be at hand in some critical emergency, or that the expert himself being human may sometimes be at fault. A famous counsel, learned in law, it is said, had three handwritings: one which he and his clerk could read, another which only his clerk could read, and a third which neither of them could read. If neither the doctor himself nor the chemist can read the prescription, what is to become of the patient? Doubtless he gets something, but is it what was intended? Nor is it only in prescriptions that the doctor's bad handwriting causes trouble. The Connecticut State Board of Health has lately felt itself obliged to call attention to "the inaccuracies in the tabulation of death certificates which result from the faulty handwriting of the physicians who fill them out." These certificates are said to present astonishing additions to the nomenclature of diseases, such as are not to be found in any recognized system of nosology. As specimens may be given such causes of death as "cardius hypohophy," meaning probably cardiac hypertrophy, "corrhasis of liver," for cirrhosis, "utrim fibride," for uterine fibroid, "lineape," for syncope, "neaesini," for uremia, "gortuitis," for gastritis. Clearly it would be to the benefit of mankind if doctors took a little more trouble to write plainly. — *British Medical Journal.*

METEOROLOGICAL RECORD

For the week ending July 29th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,872; under five years of age 1,283; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 1,789, consumption 248, acute lung diseases 248, diarrheal diseases 639, diphtheria and croup 47, typhoid fever 40, cerebro-spinal meningitis 23, whooping-cough 18, measles 11, scarlet fever 6, erysipelas 3.

From cerebro-spinal meningitis New York 9, Quincy 3, Boston and Washington 2 each, Cincinnati, Nashville, Lynn, Springfield, Brockton, Chelsea and North Adams 1 each. From whooping-cough New York 2, Pittsburg and Providence 2 each, Boston and Cambridge 1 each. From measles New York 7, Boston, Fall River, Cambridge, Lynn, 1 each. From scarlet fever New York 4, Boston and Baltimore 1 each. From erysipelas New York 3.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending July 22d, the death-rate was 18.4. Deaths reported 4,028; acute diseases of the respiratory organs (London) 149, diarrhœa 466, measles 126 diphtheria 83, whooping-cough 56, scarlet fever 37, fever 30.

The death-rates ranged from 7.6 in Brighton to 29.4 in Salford; Birmingham 21.1, Bradford 16.1, Cardiff 14 0, Derby 12.7, Gateshead 21.0, Huddersfield 10.6, Hull 13.6, Leeds 20.4, Liverpool 26.6, London 18.2, Manchester 22.0, Newcastle-on-Tyne 16.2, Nottingham 19.2, Portsmouth 16.9, Sheffield 26.7, Swansea 14.1, West Ham 14.6, Wolverhampton 11.7.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 5, 1899.

C. A. CRAWFORD, assistant surgeon, detached from the "Wabash" and ordered to the "Massachusetts."

E. J. GROW, assistant surgeon, detached from the "Massachusetts" and ordered to the "New Orleans" immediately.

M. S. ELLIOTT, assistant surgeon, detached from the Marine Examining Board August 2d, and ordered to temporary duty at the Marine Recruiting Rendezvous, New York, during leave of Passed Assistant Surgeon E. S. BOGERT, upon completion of this duty, directed to wait orders.

C. G. HERNDON, surgeon, ordered to the Museum of Hygiene for temporary duty.

J. C. ROSENBLUTH, passed assistant surgeon, detached from the "Vermont" and ordered to the "Nashville."

F. L. PLEADWELL, assistant surgeon, detached from the "Nashville" and ordered to the Bureau of Medicine and Surgery.

SOCIETY NOTICE.

AMERICAN ASSOCIATION OF OBSTETRICS AND GYNECOLOGISTS. — The American Association of Obstetricians and Gynecologists will hold its twelfth annual meeting in the assembly room of the Denison House, Indianapolis, Ind., Tuesday, Wednesday and Thursday, September 19, 20 and 21, 1899.

The Association will meet in executive session with closed doors on Tuesday, September 19th, at 9.30 A. M., for the election of new Fellows. The open session for the reading of papers will begin at 10 o'clock. Recess for luncheon at 1 o'clock P. M. Afternoon session at 3 o'clock; recess at 5.30 o'clock; evening session at 7.30 o'clock.

The morning session will begin Wednesday at 10 o'clock for the reading of scientific papers. Recess at 1 o'clock. Afternoon session at 3 o'clock. Adjournment at 6 o'clock.

At 6.30 P. M., Wednesday, the executive session will convene for the election of officers, and for such other business as may come before it under the rules.

The morning session will begin Thursday at 9.30 o'clock to continue until 1 o'clock P. M., when recess will be taken for luncheon. The afternoon session will be called at 3 o'clock and at 5 o'clock the closing ceremonies will be held. A full attendance is especially requested at the final session.

EDWARD J. ILL, *President*,
WM. W. POTTER, *Secretary*.

RECENT DEATHS.

JOHN H. GILBERT, M.D., one of the most prominent and successful physicians of Quincy, died at his home in Quincy on August 3d. He was born in Atkinson, N. H., sixty-six years ago, and was a graduate of Dartmouth and Tremont Medical Colleges. He began practice in Weymouth, where he remained ten years, when he came to Quincy. He was prominently connected with organizing the Quincy Hospital and the Board of Health In 1892 he was appointed medical examiner for the Quincy district, which position he held up to the time of his death. He leaves a widow and one son.

FRANCIS C. GREENE, M.D., a prominent physician of Hampshire County, died August 3d, at Easthampton. Dr. Greene was born in New Haven, Conn, September 2, 1827. He received his education at New Haven and his professional training at Yale. He settled at first in Holyoke. In 1853 or 1854 he removed to Easthampton and remained there till the war broke out. He was a surgeon in the U. S. Army during the war. After the war he settled for a time in New York and afterward went to Westfield. In 1868 he returned to Easthampton, and built up a successful practice. He was also prominent in local public affairs.

BOOKS AND PAMPHLETS RECEIVED.

Carcinoma of the Œsophagus with Fatal Hæmorrhage from the Subclavian Artery. By F. G. Finlay, M.D., and D. P. Anderson, M.D. Reprint. 1899.

Upon the Existence of a Minute Micro-organism Associated with Cases of Progressive Portal Cirrhosis. By J. G. Adami, M.A., M.D., F.R.S.E., Montreal.

Vital Science, based upon Life's Great Law: The Analogue of Gravitation, Agnosticism Refuted. By Robert Walter, M.D. Philadelphia: J. B. Lippincott Co. 1899.

The Medical Treatment of Typhoid Fever. The Symptomatology of Tumors Involving the Hypophysis Cerebri. By James Stewart, M.D., Montreal. Reprints. 1899.

A Contribution to the Study of Bright's Disease, with Special Reference to the Etiological Relationship of the Bacillus Coli. By Albert G. Nicholls, M.A., M.D., Montreal. Reprint. 1899.

The Surgical Treatment of Typhoid Fever. Tuberculous Disease of the Spine, Commonly Called Caries of the Spine, Angular Curvature or Pott's Disease. By G. E. Armstrong, M.D., Montreal. Reprint. 1899.

Medical and Surgical Reports of the Boston City Hospital. Tenth Series. Edited by Herbert L. Burrell, M.D., W. T. Councilman, M.D., and Charles F. Withington, M.D. Boston: Published by the Trustees. 1899.

A Text-book of Anatomy. By American authors. Edited by Frederic Henry Gerrish, M.D., Professor of Anatomy in the Medical School of Maine, Bowdoin College. Illustrated with 950 engravings in black and colors. Philadelphia and New York: Lea Brothers & Co. 1899.

Address.

ADDRESS IN SURGERY.[1]

BY ALEXANDER OGSTON, M.D.,
Surgeon-in-Ordinary to Her Majesty the Queen in Scotland; Regius Professor of Surgery, University of Aberdeen.

THE MEDICAL SERVICES OF THE ARMY AND NAVY.

In presence of an assemblage of so many representatives of the medical science of the British Empire, I have much pleasure in gratefully acknowledging the honor of being called upon to deliver the "Address in Surgery." It is a task I enter upon with a sense of responsibility, and a fear lest I should fail to do justice to the duty entrusted to me by the Council of the British Medical Association. But I take courage from the belief that you will be disposed to form a lenient judgment of any endeavor to contribute to the usefulness of the annual meeting of our Association, and because I think that the theme I have chosen for the "Address in Surgery" on this occasion is one in harmony with the high aims of our science, since it has for its design to promote the great objects for which our profession exists, those, namely, of saving the lives and diminishing the sufferings of our fellow-men.

A NEW DAY IN SURGERY.

At a time like this one cannot help being strongly impressed by the feeling that the surgical profession in our day has had much given to it, and that from it much will be required. We live in an era that can claim to be one of most exceptional, probably unique, interest. We have witnessed in it the most marvellous and rapid advances the world has ever experienced in the powers of mastering and warding off disease. We have passed through many gloomy years, in which we worked our life's work blindly and in the dark, with dread fastening on the heart as surely as the hand grasped the knife, for ever trembling before the horrors of surgical pestilence; and now we have been privileged to see the dawn of a new day when septic disease is being robbed of its terrors by the discoveries of Lister, whose great gifts to humanity, which coming generations will hereafter delight to recall, recognizing that whatever we owe to the great surgeons of the past has been but little in comparison with the benefits he has conferred on us, and through us on all mankind. And we may be sure that future ages will be very critical in their judgment of us, the present race of surgeons, and demand to know what use we made of our unparalleled opportunities, and whether we went astray amidst all the light that was given us.

THE EFFECT OF LISTER'S DISCOVERIES.

The importance of the period in which we live it would be difficult to exaggerate. For the first time in all the centuries that have flown our profession has changed from a craft into a science, a result that, though many have contributed to it, we owe mainly to Lister. Every progress made in the years of my own professional life seems to dwarf before his great discoveries, and imagination fails to grasp the limits and possibilities of the gigantic revolution which he commenced, or the unspeakable benefits it has conferred and may yet confer upon the world. The achievements of the surgeons before his day have now for the first time become fruitful and certain. Fresh fields of relieving and curing disease have been opened up at every point of our horizon, and in all the busy centres of the earth is springing up a new race of surgeons, who effect as part of their everyday work marvels of cure that even thirty years ago, had anyone ventured to forecast them, would have been looked upon as the dreams of a visionary.

THE UNSATISFACTORY CONDITION OF THE SERVICES.

While in many respects we have good reason to praise the age we live in and the way in which it has availed itself of its advantages, no one fully acquainted with the state of surgery in our land can fail to be impressed by the fact that in some quarters the changes and modifications necessitated by the progress of science are even yet meeting with obstacles that ought not to exist, and that some of our medical and surgical brethren are still hampered by systems and restrictions which must be swept away, if we are to ensure that none of our fellow-countrymen shall be denied those benefits which are now within the reach of the humblest and the poorest. I venture to believe that in the city of Portsmouth it will not be out of place — perhaps even specially appropriate, to advert to the condition of our Army and Navy Medical Services. These, since the surgical world was stirred to its depths thirty years ago by the doctrines of Lister, have been, I fear, gradually falling into a condition that cannot fail to evoke much anxiety regarding their present and future. I believe the causes of this can be more accurately pointed out than has heretofore been possible; I feel sure that, by endeavoring to do so here and now, more good is likely to be attained than would result from a similar inquiry on any less public or representative occasion; and it appears to me that the present time is suitable beyond any in the past half-century for drawing attention to the reforms that may be necessary to ensure that when the supreme moment arrives the medical departments of these services will be found adequately prepared to undertake the duties they will be called upon to discharge. We possess at the present moment an enlightened Minister at the head of the War Office, to whom we owe it that many desirable reforms have already been introduced into the Army Medical Service. We have also every reason to believe that the trend of public opinion is favorable to such further improvements as may be required in both army and navy. Recent events, too, have demonstrated that we may be unexpectedly called upon to engage with both army and navy in European or even world-wide wars, such as would put their efficiency to the severest possible test.

It is moderate and reasonable to expect that the medical departments of the army and navy shall be in a condition commanding the respect and approval of the medical profession and the public; that their officers shall be at least as favorably placed in regard to their work as their civil brethren; and that both ashore and afloat they shall be able efficiently to perform their functions in time of peace, and fully prepared for the eventualities of war. Yet no observant member of the profession, particularly if connected with one of the medical schools whose graduates used to furnish many candidates to the services of the army

[1] Read at the annual meeting of the British Medical Association at Portsmouth, August, 1899. — Abstract from advanced proof-sheets sent by the courtesy of the editor of the British Medical Journal.

and navy can have failed to observe how changed is the estimation in which they have come to be held during the last three decades. The most talented graduates have ceased to aspire to enter them, and it has by degrees come to pass that few indeed, and these as a rule of inferior qualifications, can be induced by any means to present themselves at their entrance examinations. Such a one will have noted that those medical officers who possess a few years' experience of the services, however much loyalty seals the lips of most of them and influences all, show themselves disappointed and discouraged with the professional life they have to lead, admit they have made a mistake in entering them, and would gladly, were it possible, sacrifice the years they have spent in them and quit them entirely, even for some comparatively unpromising post in civil life. He must have perceived that many of the most intelligent officers who remain in them are pervaded by a conviction that their abilities have been thrown away and their lives wasted, and that the services are not what they ought to be. He will have followed the continual endeavors made through all these years to remedy their growing want of attraction for men of ability, and the failure of these endeavors one after another. He will have learnt that year by year the medical services, especially that of the Queen's army, have become more attenuated and undermanned, so that an undue amount of foreign service, at the cost of health, is entailed on those who enter; and that hence it has become necessary to supplement the deficiences at home by employing civil members of the profession, of a class whose work unfits them for forming officers of the stamp needed in the event of war, even if their other engagements rendered it probable they would consent to be so employed. He may, perhaps, have been told that in the last year or two the post of medical officer in the army has been going a-begging, and has been hawked for presentation about the various schools and universities where suitable men might be supposed to exist. And, lastly, he may see how, when lapse of years has earned them a moderate pension, many of the medical officers, in the prime of their abilities and best working period of their lives, hasten to quit the services; but find themselves, save in the instance of a few gifted men, unfitted for any professional activity, so hopelessly have they fallen behind the acquirements of their civil compeers.

THE ARMY MEDICAL SERVICE.

It has sometimes been asserted that, in the opinion of foreign judges, our Army Medical Service is in a state of efficiency enabling it to discharge its duties in a way superior to anything that could be achieved by other countries. One must, however, discriminate. Oft-repeated experience over the very same ground has indeed taught us to conduct, in some respects, the medical part of expeditions in the jungles and swamps of West Africa, the deserts of the Nile, or the ravines of the Himalayas, in a way that probably no other power could excel or even equal. Our enemies there are poorly armed, and our casualties few. But it dare not be inferred from this that we are in a condition to deal with a war against a great power, with arms and organization at least equal to our own, in which large numbers of wounded — thousands instead of tens — must fall to be treated. That would be a most erroneous conclusion, and would not be the general verdict of either the civil profession or the ranks of the services themselves. And such of us as possess friends among foreign military surgeons, men of large experience in actual warfare, do not hear from them any such expressions of approval as would warrant very sanguine inferences. It is absolutely conclusive on this subject to recall that last year, when a deputation from the British Medical Association was received by the Secretary of State for War, its members, most of them leading authorities from our universities and medical schools, expressed themselves deliberately to the contrary effect, using expressions that ought to be well weighed as coming from those whose position enables them to form an unerring judgment. An eminent president of this Association there gave utterance to the following ominous opinion: "If there were to come a time of war it is to be dreaded that the horrors which occurred during the Crimea may be repeated." All others present spoke to a similar effect, and the Secretary of State admitted that, owing to the condition of the Army Medical Department, "only comparatively inferior men present themselves . . . the best men turning away from the Army Medical Staff . . . a very grave condition of things."

With regard to the duties in time of peace, it may be contended that these, being chiefly to maintain our army and navy in good health, are efficiently performed in the services; though I need not repeat that even these are at present carried out in the army to some extent by the aid of civil practitioners, whose other occupations unfit them for being effective and satisfactory army medical officers. But it must not be forgotten that this is not all the country expects. The duties of the Royal Army Medical Corps and Naval Medical Service involve preparation for war. This is the chief end of all departments of the army and navy; and, unless they fulfil that end, no matter how creditable they may be in other respects, they are but a pretence of what they ought to be. In this it must, I think, be admitted that they are in a condition leaving much to be desired. Attendance on minor ailments, trifling complaints, and the few serious diseases and injuries occurring among bodies of men in the prime of their age and health, selected for strength and soundness, and the other routine duties, which together constitute the whole ordinary work of the immense majority of the medical officers serving in our forces, form so great a contrast to much that would be expected of them in an active campaign against European troops that comparison between them is hardly possible. They afford the army and navy surgeon, it is no exaggeration to say, scarcely any chance of acquiring the knowledge and skill that would be demanded of him in war.

No surgeon can now, as in former days, rise suddenly out of the ranks of those destitute of special training, however eminent his natural abilities may be. He who is skilled in exercising his profession becomes so by many years of special training. No man who is but theoretically acquainted — be it in ever so perfect a fashion — with the mere doctrines of antiseptic surgery is able to step at once into the arena as a practical surgeon. He must in the first place acquire by slow and painful degrees a familiarity with methods, manipulations and procedures built up of a multitude of little details. It takes him many years to acquire these by practice, by training himself alongside of those to whom they are already familiar, by the discipline of his own

failures, and by a study and familiarity that eventually imprint them so deeply that they become a part of himself, and are carried out instinctively and unerringly under all ordinary conditions, as well as in the usual events and emergencies that continually arise in so many of the cases he treats. Septicity is an enemy of infinite variety not to be combated with success by theory alone, or by wielding a single weapon; the modern surgeon must be armed at all points, both for offence and defence, and acquaintance with his weapons and their powers is not attained save by a long course of study and training.

Even after the ordinary practice of surgery as nowadays carried out has had its foundations laid by a training in antiseptic and aseptic work, the greater part of the education of the skilled surgeon has yet to be acquired. The methods of cranial, thoracic, and abdominal surgery are necessarily, to meet the varying circumstances, so numerous, so intricate, and demand so great intellectual and manipulative skill, that only one who has spent years in constantly improving himself in them, whose mind has been fashioned by long experience and study of the problems he daily meets, and whose hands have gained by constant usage the technical facility and delicacy indispensable to success, can with impunity venture into these territories with the requisite boldness and confidence, and ensure the successful results which alone render these procedures justifiable. Such is the life-long training of the skilled surgeon of our cities and hospitals, who carries out the marvellous methods and obtains the wonderful results of modern surgery.

THE STANDARD OF MILITARY SURGERY.

A standard of work at least equal in excellence to that of the civil surgeon ought to be expected of army and navy medical officers. Senn, of Chicago, chief operating surgeon with the United States army recently in the field, and one who has done much for surgery, points this out in the following axioms:

(1) That in theory and practice military surgery is equivalent in every respect to emergency practice in civil life.

(2) That the wounded soldier is entitled to the same degree of immunity against infection as persons in civil life suffering from similar injuries.

(3) That all formal operations in war must be performed where the wounded can receive the full benefit of aseptic and antiseptic precautions.

(4) That operative interference is indicated in all penetrating wounds of the skull.

(5) That gunshot wounds of the chest should be treated under the strictest antiseptic precautions.

(6) That laparotomy in penetrating gunshot wounds of the abdomen is indicated in all cases where life is threatened by hemorrhage of visceral wounds, and the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation.

These are reasonable demands, many might ask more, but nothing that falls short of some such standard can be accepted as satisfactory. Statistics prove that of all wounds in battle there are 7.4 per cent. of the brain, 7.5 per cent. of the chest, and 4.7 per cent. of the abdomen, amounting to 20 per cent. of all wounds. There must, therefore, in the next great campaign, be an enormous field of usefulness to properly-trained antiseptic surgeons, and a fearful waste of life if they be not there to occupy it. It scarcely, moreover, requires to be pointed out that gunshot wounds of other parts besides those of head, chest and abdomen offer a field for modern surgery that has scarcely yet been entered on. No extensive campaigns have been conducted since antiseptic surgery was fully introduced, but the smaller ones have shown the need for a class of surgeons more highly trained than hitherto to carry the best methods of antiseptics into the domain of gunshot wounds, where septicity is a danger greater and more frequent than in any other class of injuries whatsoever. And I am convinced from a study of wounds inflicted by modern projectiles, on which it would be out of place to enter here, that in gunshot wounds of the soft parts and extremities a very much larger proportion of lives and limbs than hitherto can be saved, and another great field of modern conservative surgery opened up by the application of improved methods and principles of treatment in the hands of those who really know how to employ them.

THE VALUE OF THE PULSE IN DIAGNOSIS AND PROGNOSIS.[1]

BY HENRY JACKSON, M.D., BOSTON.

Though I have no new theory to advance as to the value of the pulse in diagnosis, yet I desire to bring the subject up at this meeting because to me it seems a matter of the greatest importance, and one perhaps that we do not consider as carefully as it deserves. The pulse is the final index of the vital capacity of the individual, and therein allows us to judge of the resistance to disease of the individual patient at a stated time: our patient may have a diseased heart, one much weakened by organic valvular disease or by degeneration of the muscular substance dependent upon disease in the heart itself or upon some toxemia, but if the heart is able to drive the blood through the system for the time at least death is not imminent. Therefore the pulse is, as stated, the final index of what the heart can do; so long as the pulse is of fair quality the system is supplied with blood and life is possible.

In diagnosis it is not my wish to discuss the value of the pulse in the various forms of organic heart disease, as for instance, the Corrigan pulse in aortic disease, and the small thready pulse of mitral stenosis, but rather to consider its value in the diagnosis of some of the more important and often obscure general diseases, especially typhoid fever, miliary tuberculosis, cerebro-spinal meningitis and other diseases of the brain and its membranes.

The pulse of typhoid fever is in uncomplicated cases not very rapid, rising somewhat with each access of fever, but averaging 90 to 100 or less in cases of moderate severity which run their course without untoward accident; under prognosis I shall speak at greater length of the inestimable value of the pulse as an index of the advent of dreaded complications and the exhaustion of the patient by the toxic effects of the specific organism of the disease.

In acute tuberculosis we have a very different pict-

[1] Read before the Massachusetts Medical Society, June 13, 1899, and recommended for publication by the Society.

ure; the pulse is rapid, averaging 120 or more long before the patient reaches a critical stage of the disease. In typhoid fever the pulse may temporarily be 120, but it never remains for several days at this point unless the patient is severely sick, whereas in general tuberculosis we find great rapidity of the pulse for days, and even weeks, in a patient presenting no signs of immediate dissolution, often very comfortable and anxious to be up and about the room. The rapidity of the pulse in general tuberculosis is of much value, as in both diseases the course of the temperature may be similar; in both diseases there is an absence of leucocytosis, and often the general condition of the patient may leave us much in doubt, though in the one hebetude is usually much more marked than in the other. Of course, the Widal reaction in the one case, and tubercle bacilli in the other, may if present give us an absolute diagnosis.

In cerebro-spinal and tubercular meningitis the pulse may be almost pathognomonic; in the early stages, during the time that the vagus is stimulated by a moderate degree of irritation, the pulse is slow, or rather, what is the important point in diagnosis, is slow in proportion to the general condition of the patient. To take a case we have before us, a patient who for a day or so has had a moderate fever, who is evidently very sick, with perhaps vomiting and severe headaches; yet we find a pulse of 70 to 90. If the case were typhoid fever the pulse would be more rapid; the slow pulse in the case under consideration is, however, slow, because of the direct action of the products of inflammation on the vagus. Therefore, the pulse is no criterion of the general condition of the patient. If there is added to the slow rate an occasional intermittency, we have a still greater assurance that the pulse is dependent upon some direct pathological lesion, and can by no means be considered as an index that our patient is not seriously ill, as is suggested by his general condition.

It is not an invariable rule that the pulse is slow in the early stages of meningeal trouble, but if not continuously slow we find that the rate varies much without any corresponding change in the condition of the patient and independently of the degree of the fever. I would cite two cases seen in consultation, illustrative of the value of the pulse in meningitis. Several years ago I saw in consultation a young child who had been sick several days, was somewhat stupid, had vomited, had fever, and seemed to be very sick: the pulse was 100, and intermitted occasionally. I suggested tubercular meningitis as the most probable diagnosis, chiefly perhaps on account of the pulse, a symptom that the attending physician had looked upon rather as his mainstay in hoping for a favorable issue of the case. My diagnosis was correct. On the other hand, I saw this winter a case where cerebro-spinal meningitis was certainly a possible diagnosis, and yet a rapid, regular pulse made me very doubtful as to the correctness of the diagnosis, and complete recovery in a few days convinced me of the truth of my impressions.

The slow pulse is only seen in the early stages of meningitis, as later in the course of the disease, when the vagus has been paralyzed by pressure or by disease of the nerve itself, we find an extremely rapid pulse, as the inhibitory action of the nerve has been destroyed; to use a metaphor, the engine runs with the throttle wide open.

In cerebral hemorrhage the pulse may again be of great value, when definite symptoms are wanting, as paralysis and allied phenomena; that is to say, in cases brought to a hospital in a comatose or semi-comatose condition, cases so aptly described by Mr. Ernest Hart as "drunk or dying." In alcoholism the pulse is rapid, in cerebral hemorrhage, slow; and hereby, as in a case I wish to cite, we may make our diagnosis. During my last service a man was brought into my ward by the police: he was unconscious, was tossing about the bed, was flushed. The only history obtainable was that two days previously he was found in a doorway, taken to the station house, where the diagnosis of intoxication was made, then was removed to the city prison, whence he came to the hospital. Careful physical examination showed no fracture of the skull, no evidence of external trauma; strong stimulation of the orbital nerve at its exit gave evidence of a slight left facial paralysis and the left side was moved less vigorously than the right side; the neck was a little stiff. Leucocytes 12,800; lumbar puncture negative; temperature 99°. His pulse was 40, a factor that to my mind rendered simple alcoholism impossible. The evidence of paralysis was slight and not easy to obtain, the pulse was evident. The man died the day he entered, and autopsy showed fracture of the skull and extensive laceration of the brain, with subdural hemorrhage. In view of the diagnosis that I made, I was criticised because I had not suggested trephining; I considered the matter and decided against it because the severe general symptoms without marked paralysis made it evident to me that the man was suffering from extensive cerebral trouble, rather than from total destruction of a limited area, which might be amenable to operative procedure.

Dr. Bowditch has recently called attention to the value of a rapid pulse in the diagnosis of early tubercular trouble. On the other hand, an extremely rapid pulse without evidence of serious disease may be suggestive of exophthalmic goitre, as in a case described to me in which later goitre developed.

In many other diseases the pulse may assist us in forming our diagnosis, as for instance in the early diagnosis of acute follicular tonsillitis and diphtheria, the one usually associated with high fever and rapid pulse; the other in the beginning often giving rise to only slight fever, while the pulse may not be markedly quickened unless toxemia has already taken a severe hold upon the patient.

I have spoken of the value of the pulse in the diagnosis of typhoid fever, but in prognosis we have in the pulse what I believe to be an infallible guide. In uncomplicated cases the rate of the pulse is slow relatively to the degree of the fever and the general condition of the patient. When the pulse is continuously rapid, the prognosis becomes proportionately grave with the increase in the rate, though no other alarming symptoms arise to render us doubtful as to the outcome of the case. Leaving out of consideration hemorrhage and perforation, a rapid pulse is an index that the patient is in danger of succumbing to the specific toxemia produced by the disease. The pulse is to us an index of the effect upon the individual patient of the poison of the typhoid, and is of far greater value than any other one symptom or any group of signs or symptoms.

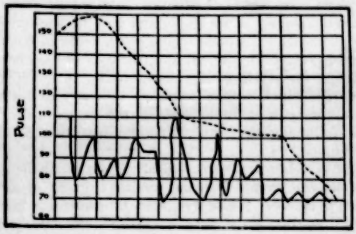
In my early student days I read an article, I think by Dr. Wilson of Philadelphia, stating that in typhoid fever the danger line was reached when the pulse reg-

istered 120; and all cases that I have seen since that day have only confirmed in my mind the great dependence to be placed upon this axiom. I have seen patients die who had only a rapid pulse as indicative of danger, while again and again I have seen patients recover where the pulse ran from 110 to 120, yet they were very stupid, had involuntary passage of urine and feces and perhaps frequent vomiting. I am so sure of my ground in this matter that in the individual case I dare to make a favorable prognosis if the pulse is slow, no matter how unfavorable the other symptoms may be. On the other hand, a rapid pulse, independent of any complication, as hemorrhage or pneumonia, causes me great anxiety.

After careful consideration of this matter in a considerable number of cases, I feel convinced that the danger line is reached when the pulse becomes 120. Of course many cases recover when the pulse is rapid, but not without a severe struggle for life.

The remarks which I make as to the prognosis in typhoid do not refer to cases complicated by intermittent diseases or by perforation and hemorrhage. In such instances the value of the pulse lies rather in diagnosis than in prognosis.

A sudden rise of the pulse without apparent cause suggests hemorrhage, especially if accompanied by a fall in the temperature. In this connection we must remember that the fever may fall by crisis, but in such instances with the fall of temperature comes a corresponding fall in the pulse, and the general condition of the patient is decidedly favorable.



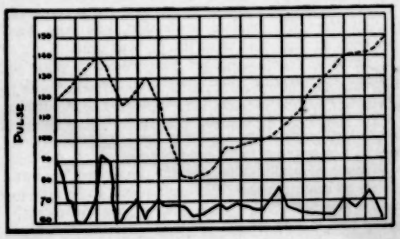
In perforation the pulse is of the greatest value, as in the following case. Last summer, at the time of my visit, one of my patients was perfectly comfortable with a pulse of 80: at half-past one my house physician, Dr. Stevens, telephoned to me that the man had a pulse rising rapidly, had pain in the right side of the abdomen, an access of fever, with an expression of anxiety. Examination showed no blood in the bowel, the pulse was 120, there was a leucocytosis of 15,000, and there was rigidity of the right side of the abdomen. The surgeon who saw him in consultation agreed with me in the diagnosis and found a perforation when he operated at four o'clock. In this case the leucocytosis was of great value, as I have never seen leucocytosis in an uncomplicated case of typhoid fever. Hemorrhage was ruled out by the rise in temperature, and the absence of blood by rectal examination.

The pulse may be rapid in typhoid fever in other complications, as otitis media and phlebitis, without rendering the prognosis unfavorable; whereas in acute inflammation of the parotid the prognosis is grave, more so, I think, than when pneumonia or pleurisy is the complicating pathological factor.

In convalescence the pulse is often rapid, and then of no serious import; it is the rule that a patient will pass through a severe typhoid with a pulse not more than 110, and when he first begins to get about have a pulse of 120 or much higher, without the slightest indication that we have any serious danger to combat. Further, many slight troubles in convalescence, as constipation, excess in diet, fatigue from seeing friends, cause a sharp rise in the pulse.

I have once seen a slow but very poor pulse in typhoid in a man that was seriously sick; examination of the heart showed that the pulse was not a sufficient index of the action of the heart, in that many beats were so feeble and inefficient that the wave was not transmitted to the wrist.

In the first volume of the medical and surgical reports of the Boston City Hospital is a valuable article upon typhoid fever, by Dr. Upham. He speaks of the prognostic value of the pulse and states that in 65 cases that recovered the average highest pulse was 108,



Case I. Parietal disease of the heart. Dotted line shows the apex beat.

while in 14 fatal cases the average highest pulse was 140.

I have looked over a large number of charts of typhoid fever cases in the Boston City Hospital, and found the same relative proportion of deaths to the pulse-rate.

Finally I wish to quote from Dr. C. Ellery Stedman's valuable essay on typhoid fever, published in the third series of the City Hospital reports. In this essay Dr. Stedman says, "Temperature for diagnosis is invaluable. For guidance during the disease I rely on the pulse." "I have seen no patient die whose pulse has not reached 120, twenty-four or more hours before death," and finally, "In these ten years the pulse has given the warning of approaching trouble even when the temperature has signified nothing untoward."

I wish to call attention to one very marked sign of cardiac weakness that so far as I know is not mentioned by most writers. Dr. Whittier has referred to it in a short article in the *Boston Medical and Surgical Journal*. Namely, a discrepancy between the rate

Case II. Dilatation of heart, probably parietal disease. Pulmonary infarction. Death. Dotted lines show the apex beat.

of the heart beat and the pulse as felt at the wrist: in many cases it is difficult to count the pulse because of its irregularity or the constantly changing rhythm, though we are conscious that a feeble pulse is occasionally felt beneath the finger, but in the cases under consideration no pulse wave is felt. This condition may be said to represent the acme of cardiac weakness and may be

responsible for some of the cases in which a slow pulse is reported in fatty degeneration of the heart. This discrepancy between the rate of the pulse and the apex beat I have seen frequently in great dilatation of the heart, dependent upon disease of the myocardium, much less often in valvular disease of the heart. I have noticed the same phenomenon in acute degeneration of the heart as seen in infectious diseases, notably in typhoid fever and in diphtheria. In diphtheria it may be seen during the acute stage, and also in the serious cases of cardiac weakness which appear late in convalescence, perhaps dependent upon diseases of the nerves regulating the action of the heart, similar to the specific neuritis which causes paralysis of the muscles of the nasopharynx or the muscles of the extremities.

The following cases give a good illustration of the phenomenon:

CASE I. Man, forty-five years. Great alcoholic excess: short of breath for six months; great general edema; cyanotic. Pulse irregular, intermittent; heart dilated; at the apex was a systolic murmur. He gradually recovered and was discharged in a month. On entrance the apex beat was 160, while the pulse was 110. For ten days the apex was much more rapid than the pulse, while later in convalescence they coincided. (See Chart I.)

CASE II. Man, forty-five. No alcoholic excess; no rheumatism. Arteries sclerotic. Heart much dilated. Great improvement at first in hospital. Then many attacks of pulmonary infarction; acute and rapid dilation of the heart, great edema and death. (See Chart II.)

These two charts are illustrative of the condition of great weakness of the heart in which a large proportion of the beats are so feeble that no wave is transmitted to the wrist.

PHILOSOPHY OF SICKNESS.[1]

BY THOMAS F. HARRINGTON, M.D., LOWELL, MASS.

IT is not my privilege to present any new addition to the long list of recent discoveries and wonderful progress with which the present medical age abounds, but rather to claim recognition for an old friend, a very old one, who, during some of the ages at least, received attention from the medical profession, but who has never been so neglected as at the present time.

In order to reach a proper conclusion, it will be necessary to consider some questions, which at first sight may seem irrelevant, but which may have more or less bearing in sustaining recognized phenomena.

During all ages there has been that mystery in the minds of the laity surrounding sickness which neither the advance of civilization nor the improved modern methods of scientific enlightenment seems to be able to dispel. We find that at the end of the nineteenth century people censure the physician on the death of his patient with as much rancor as was done in the earlier and savage ages; not because the physician was unable to save the patient from death, but because he did not have knowledge of the power to cure the disease. Is it not just and proper, therefore, that we members of a profession to whom such power is ascribed, and who not unfrequently encourage such a belief by our private conversation, acts and publications, should try either to earn to the best of our ability the compliment implied, or else stand before the world in our true light, stripped of all false coloring and chicanery.

That medical science and art has made wonderful advances tending to the alleviation of human sufferings and to the prolongation of life is admitted by all; that many diseases are yet beyond the reach of human skill must also be admitted; but that there is in every sickness a quality of body or mind, or both, which is capable of recognition and influence from without seems to have escaped observation. Many physicians, it is true, in all ages of mankind, have felt its power in the treatment of sickness, but they have either ascribed the result to some agent employed, that is, a cure, or to the ingenious philosophy of homeopathy, as lately formulated by Dr. Charles S. Mack, and reported that the patient "recovered."

I have not the time at this opportunity to introduce any of the various theories of metaphysics, concerning which men most eminent in sciences have differed. It would be presumptuous for me to even select one of the many advanced. It will be sufficient to choose certain admitted dogmas from many of them in so far as they have, in my judgment, any bearing on the philosophy of sickness. Ancient and modern philosophers and scientists have ever struggled with the one factor which concerns us in the consideration of this subject, namely, personality. Many theories have been promulgated, schools founded and creeds erected at various times throughout many ages. It does not concern us much, as physicians, whether empiricism or transcendentalism, idealism or materialism is the accepted philosophy of to-day; whether we believe in Darwin, Spencer or Pasteur; whether one part of the brain or another is concerned in our mental acts; whether we compare our physical movements to a message over telegraph wires or whether the brain is the seat of the soul; all these are questions of indifference to the physician in the appreciation of individuality; the one truth shines forth, that man possesses an identity, which is neither wholly physical nor wholly psychical, but which is both, often acting through the ethical life and often independent of it — physical because it has a bearing on results which we associate with others; psychical because it is limited to the one being which, as Lotze says, is capable of being affected and producing effects. Thus there is in every person a dual person which is susceptible to change like its physical self, but which cannot be separated either in whole or in part from the living physical body — a being which, while in itself cannot be explained nor influenced in the sense that physical bodies are, yet can be explained and influenced indirectly, that is, by connecting it with the physical self, a sort of parallelism between the two (Münsterberg). That this individuality has not been capable of exact localization and description is no argument that it does not exist, for if such a position were true, what would become of many of the sciences or departments of knowledge? Even truth itself is not always possible of demonstration.

Nature is constantly giving us proof that things are different than they seem; she demonstrates that while the earth under our feet is at rest and immovable, yet it is in motion more rapid than particles of dust in the fiercest whirlwind; we believe that sound and color are such, yet we cannot explain why, unless we fall

[1] Presented to Section on Practice of Medicine at American Medical Association Meeting at Columbus, Ohio, June 6-9, 1899.

back on our senses, and that is just where we find the proof of the individuality in our fellow-men. We cannot perceive this quality in man as readily as we can the qualities of physical science, yet it must not only be perceived, but appreciated, if we are to do full justice to our patients. As man is superior to animal in appreciation, so there may be a difference among men as to the quality and quantity of appreciative power each possesses; that all mankind has the power of appreciation is too well proven to need argument. We are accustomed to argue causes from the effects; so in like manner are we able to conclude from the products as to the power which acted; these products in man are individuality. If we do not recognize the individual in sickness, but rather view sickness in reference to those causes or conditions we know of (that is, pathological or others), we are apt to ascribe certain conditions to these causes rather than ascribe them to unknown causes; hence error, and according to the degree of our ability to describe or the activity of our intellect, we sustain or formulate new theories, diagnoses and diseases, all resting on the same unsteady foundations, which must necessarily fall, as no hypothesis which is not founded on truth can prevail.

It would be as reasonable to deny that man possesses the power of speech at birth, because he did not exercise it then, or that man has will or consciousness, because an anatomical description is wanting, as it would to assert that man does not possess personality. When we see a frail, emaciated child withstand an attack of disease of a uniform type which proves fatal to another child with every condition as near similar as it is possible for two sicknesses to be; when we see poorly-nourished, hard-working women pass through a difficult labor, while others, with every advantage which wealth can procure, succumb to normal labor; when a man over ninety years of age, whose mental faculties have been most energetically applied, submits to a serious surgical operation without an anesthetic; when celebrated army surgeons ascribe nostalgia as a cause of death among volunteers in the army, then indeed must we recognize some influence other than mere physical traits in the human system.

The present tendency to explain the phenomena through the nervous system is, in the majority of cases, a makeshift which is as uncomplimentary as it is unscientific. Stamina, vital force, faith, idiosyncrasy have all been offered to explain the results, and while it may be impossible to fit a term which will meet all objectors, the one fact remains, that there is *something* present. Again we see this self, this personality, exhibited in another form; for example, self-discipline, sagacity of mind, decision, honesty of character, all of which require more than a mere physical or psychical origin for the phenomena manifested. It implies a plurality in the individual, one and the many. If we believe in the present accepted theory that disease, exclusive of mechanical and traumatic disease, is due to a sort of auto-intoxication arising from changes in materials normally present in the body, and not due to any new material from without the body, and that this alteration (disease) is subject to the same laws, in a degree, which regulate the organism in health, is it asking too much to admit that those qualities of mind and body and soul which we recognize and admire in men in health may also change in sickness and become different in every essential, and as they are often the ruling forces in health, so, too, they may become such in disease; in fact, they may be one factor in sickness requiring treatment.

Bouchard says that "man's urine contains daily enough poisonous matter to cause the death of the person, if it were not excreted." The importance of attention to the condition of the intestinal canal in nearly all the general diseases is well recognized.

In health man is constantly changing in his composition, never the same at any two moments of time; this is likewise true of disease. Disease cannot be looked upon as a fixed science, for while many of the phenomena in disease are fixed and positive, yet when viewed in the totality many constituents are wanting. No two individuals see disease with the same image, yet this does not exclude a classification of disease, nor the recognition of types. The picture, that is, the diagnosis of disease, is never viewed with reference to one particular organ change, to the exclusion of all other organs and changes, but our conclusions are based on the whole picture before us; in other words, the patient. Now, if this be true in regard to the physical being, why should it not be true of the inner self?

A celebrated artist credits his great success to the fact that he never paints a picture until he learns the traits and character of his subject, and during the sittings he talks to the subject on those topics which have a personal interest to him (the subject); in this way he produced a picture which was much praised for its naturalness; it reflected the true inner self as well as the exterior physical features.

What is the very thing which makes one physician more successful than another in the care of patients? The family say it is "faith" or "confidence," while we often think it is our superior knowledge. The truth is, that the successful physician is he who perceives and appreciates the whole patient, and uses the knowledge gained with the proper judgment, the physician who treats the patient as well as the disease.

The stimulus given the patient by his belief that his physician possesses an extraordinary power or insight is often sufficient to awaken the potentiality in the inner patient which shows itself in the physical self.

When we view the past history of medicine with its false notions, superstitions and beliefs, with its crude methods of research and investigation, and compare the teachings and doctrines of Hippocrates with those of our age, with all the advantages which we possess, it must with truth be admitted, that in many respects, the advance has been very little, either to the profession as such, or to the science of medicine. Much of the confusion in the diagnosis and treatment, as well as in prognosis, which prevails today has been brought about by neglecting to look deeper than the physical aspect of the case presented. The overdrugging treatment of patients, which is now happily giving way to rest, dietetics, and conservation of patients' strength, was due more to physicians giving their thought and energies to the disease and thereby neglecting the patient, than to any particular demand for poly-pharmacy. We find the cause of this chiefly in (1) improper medical teaching; (2) specialism.

If we take any of the medical colleges of the day and examine the courses offered to the students, it is evident at once that there is yet much room for improvement in the system employed. The advanced step taken at Harvard and others in the standard re-

quired, both in entering and in graduating, augers well. Yet, to claim that no man who is not a college graduate can become a successful and creditable member to the medical profession, is carrying the analogy to an absurdity; there are too many living proofs to the contrary.

While the present system of "electives" prevails at the colleges it is possible for a boy to graduate in arts, and yet not select, during his whole course, even an inhibitory study to his medical course. True, he is able to anticipate some of the first-year medical studies, but that is merely for time-saving purposes. I believe in the elective system as the one calculated to give the greatest good to the greatest number; the defect is not so much with the system as with its application. A university, to have any right to such a title, must teach universal knowledge; anything less is not truth, and to whatsoever the pre-medical training of the man is deficient, just to that degree will his usefulness as a physician be impaired. It is not the addition of new studies that is required, but rather the awakening of the student's mind to the proper appreciation of the courses now offered. The great importance of physiology, anatomy, pathology and histology in the study of the human system (physical) is an axiom of medicine; the advantages of laboratory researches in neurology and brain diseases are more apparent every day, enabling us to trace many phenomena to almost a certain origin, but it is to the teaching of clinical medicine with its auxiliary, theory and practice, that we may, with profit, look. I take the system used at Harvard because I think it to be the highest type, as well as being my Alma Mater. After witnessing and performing the most conclusive experiments on animals, after learning thoroughly the etiology and symptoms, as laid down in all the text-books, the student sees patients by the hundreds at the clinics and hospitals, with every opportunity to become familiar with disease in all its details; he hears the patient's history, past, present and future; inspects, auscultates and percusses the patient to his heart's content; demonstrates to his teacher and fellow-students the objective and subjective signs of the disease; a most elaborate system of diagnosis by elimination is gone through and the patient is passed on to make way for the next patient. After months and years of this routine, he passes his examination and receives his reward — *Medicinæ Doctor*. Now what are the results of this training? While there may be no question but that the experiments performed upon animals in the laboratories are true, scientifically, and also, that they have been a great blessing to humanity, on account of the knowledge gained, yet the physician who looks upon his patient in accordance with the conclusions drawn from such experiments, to the exclusion of all other knowledge, sees a being who is born, grows, eats, drinks, walks, reproduces his kind, and dies; he compares his organs, his structures, his functions, his faculties to those of the animal, and practises medicine accordingly (Newman). Such a man would not be taken as the type of the true physician, yet one has to but read some of the medical journals of to-day to see that it is not always the graduates of unrecognized schools who often give current to such views. The student does not see the man, but rather the disease; he views him wholly in his relationship to those known causes with which he is familiar, and neglects to see him in his higher, truer self. He has, perhaps, seldom seen his patient more than once, and has never had a patient from the beginning to the end of an illness. The student should be taught that there are no fixed rules applicable to all patients, even in the so-called type of the disease; that each patient is different, in a degree, from any other patient ever seen; that hereditary, environment, sex, age, climate, occupation, etc., all have their bearing on the patient in certain particulars, but that they are not the only factors; teach him to look for the true patient, the individual, and while it may not be as easily discerned nor demonstrated as physical factors, yet it nevertheless exists in every person. If we neglect to appreciate this quality in our patients, our knowledge of their condition and our usefulness as physicians are limited to just that degree. Teach the student the faculty of looking for the self in every patient and of forming some estimate of its influence, for even if the conclusions be faulty, yet they are better than none, and in time such a habit will bring its reward.

One of the surest ways of learning the real patient is for the student to become, metaphorically, the patient. Although it cannot be expected that every physician should be a scientist, so to speak, yet, the cultivation of the practice of looking at his patients in the manner implied above must make him more systematic in his observations and enable him to place phenomena in their proper position to known facts. The microscope does not dispense with eyes; the lecture-room and text-books will help him, but he must be true to himself, he must be a party in the work. It will develop that quality which is most necessary to the physician, that is, judgment; not the faculty of avoiding mistakes, but rather that which enables him to seize the strong points in the case before him.

Have the student study his patient and the disease thoroughly, then come before the class and submit himself to a method of questioning and cross-examination from the professor, the student acting the part of the patient in the subjective sense, supplying the necessary objective information to make an intelligible picture; after which the students make their diagnosis to the professor. Such a method would give the young physician more practical knowledge and greater confidence in meeting his patients in private practice.

Until medical schools have their own hospitals, with all the advantages that that implies, it will be necessary to go on more or less in the same routine as at present; but the needs of a school-hospital could be somewhat minimized if the system now used (Harvard) in the obstetrical department, of giving the students private cases in patients' homes, with consultations (demonstrations) under one of the teachers, was extended to clinical medicine; disease can be demonstrated and studied in schools and hospitals, but sickness can be best studied and appreciated in the homes. Every physician is familiar with the self-confidence manifested at our first confinement cases in private practice, and the almost entire lack of confidence we experience on our first medical cases. Nothing could be a stronger argument in favor of benefits of the home-patients method of treatment.

Much has been written on the injurious effects specialism is having on the practice of medicine. While there is no doubt but that society and science is benefited by splitting medicine up into various parts, and while it is, perhaps, true that such subdivisions are necessary, yet the physician who gives himself

wholly to this practice must of necessity go backwards, and we see him carrying his views into cases in which they are not applicable; the result then becomes detrimental to science and society. The tendency of young graduates to rush into specialism, without any experience in general practice, should be condemned by all who hope to see the medical practice reach the high plane for which it was destined. Zamolxis puts it well when he said that "As you ought not to attempt to cure the body without the head, or the head without the body, so neither ought you to attempt to cure the body without the soul, and this is the reason why the cure of many diseases is unknown to physicians of Hellas, because they are ignorant of the whole, which ought to be studied also, for the part cannot be well unless the whole is well" (Allbutt). The overcrowded condition of the medical profession; the age at which men graduate in medicine; the belief that the road to fame and wealth is more direct and shorter in specialism; the microscopic tendency in the question of diagnoses; and the association of the general practitioner with "old-fashioned ideas" in the minds of the new physician, are some of the causes tending to modernize the practice of medicine. That a reaction has already set in is evident from the public addresses of those competent to speak, also from the position taken by our leading colleges on the question of higher medical education, making a university of medicine of what was formerly a school. Then, again, the marked progress in the general educational standard of society of to-day, and what that promises for the future, are almost conclusive that the time is not far distant when more will be demanded of the physician than that he be a part and not the whole, that he combine those traditional qualities of the old physician, reinforced by modern discoveries, with a systematic knowledge of all those sciences necessary to complete the whole, perhaps less in amount in special lines than is now held by some, yet sufficient. The physician of the whole body and mind, who from his knowledge of nature and man and soul is the only one entitled to that name — Physician.

IMPROVEMENTS IN ARMY MEDICAL SERVICE, SUGGESTED BY EXPERIENCE IN THE LATE WAR.[1]

BY WILLIAM H. DEVINE, M.D., SOUTH BOSTON,
Lieutenant-Colonel and Medical Director, Second Brigade, M. V. M.; Late Major and Brigade Surgeon, U. S. V.

THE object of this paper is not to criticize the medical service of the regular army or National Guard, especially of our own State, whose medical service at the commencement of hostilities was almost all that could be desired, considering that the volunteer militia had not seen active service for over thirty-five years. It is only by experience that we can approach perfection in any branch, and my idea is to suggest methods for improvement in our service.

As surgeon in charge of a large field hospital, I have had exceptional opportunities to observe defects in our present system. No matter what advancements are made in National Guard medical service, one cannot fully utilize them in national as in State service, for the reason that in the former we are depending on the efficiency of superiors over whom we have no control; but the State training of its medical officers in a body and the individual training cannot fail to produce good results. To illustrate this point: The country has another war; Massachusetts sends to the front, as it recently did, medical officers well trained in the duties of their department; each regiment, as in this war, is sent to a brigade composed of troops from different States, whose medical department may be controlled by an officer of little experience in caring for large bodies of troops. Necessarily, the inefficiency of the head of the department must hamper the work of our medical officers; for instance, take the matter of supplies; if the superior officer does not furnish the proper medical supplies, the command must suffer; but with subordinates who thoroughly understand red-tape the career of the inefficient will be anything but pleasant. Then again the surgeon is apt to be detailed from his organization for special duty, but wherever he goes his individual training will help him.

What excuse have I to offer for bringing this subject before our Society? I have no apology to make; it is the proper place. Our profession is responsible to a certain extent for the men it sends to the medical department. For the work of our physicians on the field, the profession at large share with the military authorities the criticism which may be just or unjust, and it seems to me highly proper to interest the profession in the matter. The material, medical, surgical and hygienic, procured in war should be placed in the hands of the best professional talent, in order to reap what profit there is to science and for the benefit of mankind. For the information of those not familiar with military organization, I will state that medical officers in an army corps (containing about 25,000 men) were distributed about as follows: one chief surgeon of corps, with the rank of lieutenant-colonel; two division surgeons, with rank of major; six brigade surgeons, with rank of major, one for each brigade; nine regimental surgeons, with rank of major, one for each regiment; eighteen assistant surgeons, with rank of first lieutenant, two for each regiment; one assistant was detailed for special work at division hospital, or other duties.

So many details were made from medical officers for special duty that most organizations were handicapped by being short of physicians. Brigade surgeons existed only in name. They were detailed to take charge of division hospitals and other special duty. The senior regimental surgeon was acting brigade surgeon. Contract surgeons were detailed to take the place of these officers in many cases. Many of these contract surgeons were first-class men, impelled to offer their services through patriotic motives, and I shall always recall with pleasure the able and self-sacrificing devotion of many to their duty. These men were not examined for their positions, and, consequently, some got into the service who had nothing to recommend them but their political influence. For obvious reasons every surgeon ought to be commissioned in the service, not for any vain glory, but in order to render all amenable to the same discipline, and to stimulate pride. I cannot see the reason why men should serve in this department without commissions any more than in any other. A reserve staff could be formed of physicians who came with good professional recommendation and passed an examination in the different branches of the science. If I can judge by the eagerness of my medical neighbors to go to the front, I think the flower of

[1] Read before the Massachusetts Medical Society, June 14, 1899, and recommended for publication by the Society.

the younger members of the profession could be secured for this honorable and important work. When a medical officer was detailed for special work, as, for instance, where one considered an expert in yellow fever was hurried to the front, a member of this reserve staff who had shown his qualifications for the work should be detailed to take his place. He could assume his new duties feeling that he would be respected by officers and men, holding the commission which entitled him to it. Of course, it is only fair to mention that the apparent urgency was so great and the heads of departments so busy that to make provision for this method was perhaps not deemed expedient.

Had our troops in this Commonwealth gone to the front in brigades which had long been organized, their service would have been even more efficient than it was, with medical and every other department properly equipped and an ambulance corps that has been a pride to our soldiers. Our leaders in other departments of the militia service as well as the medical are, and always were, men of ability and action. As intimated in an early part of this paper, surgeons in their respective States may have received excellent training, but in the field may be handicapped by an officer whose experience has been confined to a small military post; much of the executive ability of the former is lost by this, but even under these circumstances their training renders their services valuable, although not so much so as if they performed duty with their own organizations.

You are familiar with the noble work of the Massachusetts Volunteer Aid Association. The surgeon superintendent of their ship *Bay State* was formerly Surgeon-General of this State, and his successful management suggests the feasibility of calling to our aid in emergencies the services of physicians who have served the State in its medical department, but who have retired after nine years of continuous service, or another class that have severed its connection with the militia for various reasons. In looking over the adjutant-general's reports of this State for the past ten years, I find the names of at least twenty surgeons who have left the service. Most of them would be proud to give their services if asked, and I can answer personally for several, who have told me that they would have served if they could have procured an appointment.

I recommend that in the future, a reserve staff be formed of all medical officers who have served in the militia. These men have received some training in the duties of the medical department and if not required in the active work of a campaign, their advice and relief work at home would be of great value. The skeleton of a first-class Volunteer Aid Association could be formed by these officers, controlled by the surgeon-general, and its official connection with the service would be of decided advantage. A military organization should be able to take care of itself in every department.

At least one surgeon in each brigade, and better if in each regiment, should be selected for his skill in surgery. You can see the importance of having a trained surgeon, a specialist in surgery, in an organization that may be engaged in battle where major operations requiring great skill may be performed. The camp of instruction is not the place to teach surgery, neither is the battlefield the place to learn. In the school suggested men will be taught surgery, particularly that which relates to gunshot wounds and other injuries likely to be met with on the battlefield, but this instruction cannot make them skilled surgeons; a special aptitude is required, and we should have no difficulty in getting at least one first-class surgeon in every organization. A special surgical examination on admission could be given to applicants seeking those positions.

A bacteriologist could be attached to each brigade or division. The reserve corps before alluded to could furnish specialists in this line. With thoroughly equipped laboratories, they could be of inestimable value in aiding the surgeons to diagnose doubtful cases of malaria and other diseases, besides furnishing valuable aid in compiling the medical history of an army, and adding to science. A division hospital, as its name indicates, is a hospital for all the sick soldiers of the division, that is, for those ill enough to be confined to bed. In this campaign regimental hospitals were practically abolished and all the hospital equipments called in at least in one Southern camp to form the division hospital. This met with such vigorous and just opposition from the volunteer surgeons that a compromise was made and each regiment allowed to retain two cots in its hospital for emergency and observation cases. Towards the middle of September the wisdom of allowing regimental hospitals was clearly seen and provision made for the care of soldiers in their own regiments. I think most volunteer surgeons will bear me out in the statement that division hospitals are failures in the broad sense. There should be a division hospital for special cases, where major operations could be performed and where cases requiring treatment of a specialist could be referred; also a contagious hospital. The regimental surgeons should treat their own men; their sick should be nursed by their own comrades; the question of discharge for disability and sick furlough should be settled by the regimental surgeon. The surgeon would not only be responsible to his superiors for the care of his sick, but he would also be responsible to his State and his neighbors. With division hospitals the regimental surgeon has but little responsibility; he becomes a mere transferring agent for division hospitals; an admitting physician, so to speak; his men lose confidence in him. In the future, if division hospitals exist, they should be thoroughly equipped with everything necessary to form a first-class field hospital, and not depend upon the equipments of the State to furnish them. I do not wish these remarks in regard to division hospitals to be considered a reflection on any individual for their introduction in this campaign, for it did seem before and early in the war that the system had much to recommend it; but I base my opinion on my own observations and those of many surgeons. However, a longer trial of these institutions may convince us of their superiority. The failure to supply these hospitals with suitable equipment is explained by the fact that the demand for medical and hospital supplies for such a large army was so great that it was impossible to furnish them at such short notice.

In the National Guard we have not the organization for a division hospital, but it would be well to practise more for the perfection of brigade hospitals, which really are division hospitals on a small scale, in order to perfect ourselves in the working of larger

field hospitals. We had so little sickness during our short encampment in this State that we had but few cases for our brigade hospital at South Framingham.

The encampment, care of men, etc., should be the same as in actual war; the drinking water *should be filtered, no matter how pure*, in order to accustom the men to it, and to impress on their minds the importance of such a procedure. A garbage plant is important; a regiment should be so accustomed to active service methods that it could step gracefully from the militia into the national service. To be sure, there would be more or less recruits in every organization at the commencement of hostilities, but the skeleton of the perfect machine would be there and would quickly adapt itself to campaign work. The soldier cannot be produced in a month any more than the mechanic.

How much have we improved our medical department since the Civil War? And in what ways shall we improve it in the future? As far as the volunteer service is concerned, we have made a decided advance. Much interest has been taken of late years in the progress of this work. Education of medical officers coincident with general medical education has contributed not a little. Antisepsis has contributed greatly, but of course we cannot claim all improvements, such as antisepsis, for the medical department; but we can claim it for our profession, and after all, what we claim for our department is simply a claim for our profession, for there is no title we are so proud of as plain doctor.

In 1892, the Association of Military Surgeons of the National Guard was formed, and in 1894 the scope of the organization was enlarged by taking in the medical officers of the United States Army, Navy and Marine-Hospital Corps, and the name changed to Association of Military Surgeons of the United States. This Association meets annually, and many valuable papers on all subjects pertaining to military medicine are read and discussed. The convention lasts three days, and the exchange of ideas and the interest awakened in subjects have done much to advance the medical service of the country.

I do not wish to take all the credit for suggestions here made. Some are original, and many are obtained from my associates in the militia, particularly the superiors with whom I have had the good fortune to serve.

A few quotations from the surgeon-general's reports will show the interest taken in our State medical service. Many of the suggestions have been acted upon and have borne good fruit. I trust that ere another year has passed the volunteer militia will have profited by the introduction of all these improvements.

Surgeon-General Kittredge in 1893 recommended a physicial examination for recruits, that a gymnasium be established in every armory, and a systematic course of athletic exercises be prescribed and carried out under a proper instructor, and also that a system of feeding troops in conformity to military usages be adopted, together with an emergency ration.

Surgeon-General Burrell's Report, 1894: "In a few of the States the medical department of the National Guard has been placed on a permanent footing by being made a staff corps. In one State, when a vacancy occurs in the medical department it is announced in the public press that a competitive examination will be held for such appointment, and the best man is commissioned as an assistant surgeon, and is sure of promotion and full surgeonship, and possibly a directorship. Whether it were wise or not to bring about this condition of affairs in our own State has been a matter of serious consideration; but our present system and the personnel of the medical department of this State are in such condition that it has not seemed wise to me to seek such a change, at least at present." (Some of the duties of medical officers, M. V. M.)

Recommendations by General Burrell, Surgeon-General's Report, 1894: "That a physical examination of recruits be made mandatory; that the surgeons receive compensation for the examination." Dr. Burrell and his successors have worked hard for the attainment of this, and now the examination of recruits is mandatory, and the surgeons will receive moderate compensation for their services. Since the plan was started by Dr. Burrell our recruits have been examined to some extent through the generosity and unselfishness of our medical officers, who have worked zealously for the State without pecuniary reward, but in the future this examination will be done in the thorough and efficient manner such important work deserves, and the surgeons receive some compensation.

In the late war many officers and men enlisted who were indebted to their States for their military training, but being rejected on physical examination, were consequently unable to make any return for this training.

The war has taught the lesson anticipated by General Burrell and his successors, and in the future our militiamen will be ready physically as well as patriotically when their country calls for them.

Surgeon-General Burrell's Report, 1894: "I am convinced, from personal investigation and from reports of our medical officers, especially that submitted by Lieut. C. W. Galloupe, that a large saving in illness, even of a temporary character, might be made at the encampments of State troops by the State providing suitable food. I would by no means recommend an army ration, — not but what an army ration in itself is an excellent bill of fare, but it is not adapted to State troops who go into camp for a short time. Troops should be provided with plain, wholesome food, and this should be furnished by the State."

In 1894 General Burrell adopted a system of blanks modelled after those in use in the army, but so modified as to meet the wants of the State service.

A school for medical officers was started during the régime of Surgeon-General Burrell and is still in existence; one or two sessions have been held every year, and many interesting papers on subjects of military medicine and surgery have been contributed. Dr. Burrell obtained permission from the Surgeon-General of the United States for members of our organization to attend the school for regular army surgeons in Washington, but for obvious reasons advantage was not taken of this privilege. The starting of our school by Dr. Burrell was a step in the right direction, and the continuation of this idea on a larger scale desirable, but the formation of a special school for militia medical officers, and conducted by medical officers, is impracticable, and I would therefore recommend that a professorship of military medicine be established in the different reputable medical colleges of the United States. It seems to me that this would be a great step towards

approaching perfection in military medicine and surgery. The different branches of these subjects, including hygiene, transportation of the sick and injured, the management and organization of field hospitals, red tape of the service, etc., could be taught in a course of lectures extending over one year.

Even though the knowledge thus gained were never used in army service, it would be no burden and would prove useful in civil practice. The knowledge of red tape acquired would give the student an insight into methods which would be of some benefit to him in conducting his ordinary business affairs. When the tocsin of war sounded again it should find the medical profession, as a body, ready to tender its best assistance, without the preliminary training which is now required in order to do effective work.

In the late war our profession as a whole did noble and efficient work, and whatever may have been lacking in its effectiveness was not due to ignorance or incapacity as far as ordinary professional duties were concerned, but to inexperience in military medicine. It has been suggested that the National Government establish a medical school for army surgeons, including militia surgeons, to train physicians for the army. This is unnecessary, as the course now given in Washington to regular army surgeons before they enter their career is sufficient. In any great emergency, such as the Civil War and the one through which we have just passed, volunteer surgeons must be depended upon for their share; they cannot devote the time to take a course at some special school remote from their homes, and the method I advocate would be in conjunction with their regular medical training. The advantages of this system are obvious. The country would then have a large body of doctors fitted for the medical service ready at short notice. Until such a system is inaugurated, in fact well established, there should be a course given to medical officers of the National Guard in medical schools or post-graduate courses, the latter consisting of at least thirty-six exercises in the form of lectures, or one a week for the school year. A school like Harvard could give one or two exercises a week in its regular course, or the State could provide for instruction in post-graduate schools. This system would give an opportunity to medical officers to derive decided benefit from connection with the militia. At present the advantages are not professional but almost purely social, excepting perhaps the slight experience derived from practice at State camps. By strict entrance examinations, embracing general medicine and surgery, the Massachusetts Volunteer Militia has maintained a high standard in its medical department, and it is the hope of the writer to see the whole service of the National Guard brought to the same or even higher degree of efficiency, by suggestions recommended in this paper.

I quote from the late Surgeon-General Forster: "Voluntary examinations of recruits are maintained in some commands; to secure the greatest efficiency of our State troops, such examinations should be mandatory with all, and I so recommend." To establish company bearers as part of the militia system of the State, he requested the following paragraph to be incorporated in general order No 6:

"Company commanders, with the concurrence of the senior medical officer of the command, will designate four privates for instruction as litter bearers. They will be known as 'company bearers' and shall be instructed under the supervision of the medical officer (senior) at least one-half hour daily while in camp and at such other time during the year as the commanding officer may deem advisable, in the duties of litter bearer and the methods of rendering first aid to the sick and wounded. This special instruction will not relieve them from the performance of all regular (their) military duties. They will give first aid to the sick or wounded or carry them to the rear until relieved by members of the ambulance corps or a medical officer. When so relieved they will immediately join their companies.

"When on duty where their services may be required they will wear a distinguishing mark — a red brassard around the left arm, just above the elbow."

Our present surgeon-general has well sustained the record of his predecessors. His earnestness and zeal in seeing that his medical officers were well supplied with everything needed in their department will always be kindly remembered. His motto, "There is nothing too good for Massachusetts soldiers," has been lived up to in the present campaign.

In his recommendations this year Surgeon-general Blood says: "I would recommend that each Massachusetts Regiment of Infantry, M. V. M., have one surgeon with rank of major, and two assistant surgeons with rank of first lieutenant." In case this increase is made, the extra surgeon could be selected for his surgical ability.

"Of the nearly nine thousand troops at one time or another encamped at Framingham during the summer, only one serious case of illness occurred. This seems a remarkable record, in view of the great amount of sickness of the United States Volunteer soldiers in Camps Alger, Va., Thomas, Tenn., and in camps in Florida. This, I believe, can only be accounted for by the supposition that the sanitary conditions were better at Framingham than at the camps mentioned, and that there was a better supply of pure water; this was probably true."[1]

Emergency lectures following the course adopted by the Massachusetts Emergency and Hygiene Association have been given with more or less regularity to the different organizations of the militia the past seven or eight years. The Association has furnished skeleton charts, etc., in fact everything required for a course of instruction in first aid to the sick and injured; it has also furnished diplomas to soldiers who have passed satisfactory examinations and have been recommended by their medical officers. Too much praise cannot be given this noble Society for its good work. Prevention of much suffering and even loss of life amongst Massachusetts militiamen were due to the instruction received in first aid by the militia of the Commonwealth. Dr. Otis H. Marion has done much to advance this work in the militia.

To this course I would add instruction in camp hygiene, the prevention of contagious disease, etc., embracing policing of camp; personal cleanliness; the importance of reporting venereal disease to prevent its spread by drinking vessels and other means; care of water supply to prevent pollution; bathing, clothing, ivy-poisoning, and kindred subjects.

No rules and regulations to prevent disease can be carried out without the intelligent co-operation of officers and enlisted men. An officer high in command in United States Volunteers told me that he saw a

[1] Surgeon-General's Report, 1898.

soldier lying on the ground and drinking from a stream that had been contaminated nearer its source by washing, bathing, etc. There was no need of this individual endangering his health by drinking from the polluted stream; there was an abundant supply of pure water in each regiment. Such reckless individuals form a small part of the volunteer force; the great majority are earnest, patriotic men who are anxious and willing to learn and practise everything which conduces to their physical welfare. For years I have believed in the importance of individual instruction to officers and men. With this end in view I advocated and, with the permission of the Surgeon of the Ninth Massachusetts, gave instructions to officers and men in the above-mentioned subjects. Each day the members of one company were instructed until the twelve companies of the regiment had been educated on these important matters. The fact that disease was more to be feared than bullets was impressed on their minds and with good results. In two months' service in this country there was not a single case of typhoid in this regiment; in fact I don't think it can be justly said that Massachusetts brought any of the typhoid cases to the South.

This Ninth Regiment, according to Lieutenant-Colonel Weaver, the regular army officer who mustered it into the United States service, was an exceptionally fine body of men physically. Every care was taken to prevent disease, but while in Cuba the hardships during the siege of Santiago were so great that it was impossible to carry out measures for the prevention of disease.

Since writing this paper I have seen various quotations in newspapers and medical journals from high medical authorities, advocating the education of line officers in matters pertaining to camp hygiene. I have the satisfaction of knowing that I have not only advocated but have practised it in the late war and with results that have fully demonstrated its importance.

The ration must be improved upon and adapted to the tropics. Expansion means an army in tropical regions, and consequently it will have to adapt itself to the surroundings. This hardly comes within the scope of this paper. No doubt the military experience of our troops in the Philippines, Porto Rico and Cuba has taught this lesson, and in the near future we shall probably see a ration adopted that will fully meet the demands. The United States Army ration as it stands to-day has stood the test of experience for many years in this country, and I believe gave good satisfaction in camps of instruction.

By direction of President McKinley a special order regarding the food supply of the United States Army in the tropics was recently sent to commanding generals at Manila, Havana, Cuba and San Juan, in order to determine what alterations, if any, in the established rations would be conducive to the better health of troops serving in tropical countries. Each of these officers is directed to institute a board of three officers serving respectively in the line, medical and subsistence departments, to examine into the subject of any desired changes in the ration for the troops serving in his command, and to cable the results of such inquiry to the Secretary of War. It is fair to presume that this will result in great improvement in rations for our troops in tropical climates.

For many years this State has maintained a well-organized ambulance corps under the command of an able and efficient officer.

The commencement of hostilities found this Government with no provision made to take this or other like organizations into its service.

To prevent the possibility of again losing the valuable services of such well-trained men, I would suggest that one or two men be detailed from each company of each regiment for instruction in ambulance corps. I would also deem it advisable to consider the value of a corps of trained female nurses in connection with the militia.

Perhaps there is no position in the army more unsatisfactory than the surgeon's; he has no power to command; everything must be done with the approval of his commanding officer; he is censured for the health of the command, when perhaps he has made every effort to do his duty, Certainly this State has a medical service of which it can feel proud. The examinations for admission to the medical department of the Massachusetts Volunteer Militia since 1874 have been very strict, embracing the following subjects: anatomy, physiology, chemistry, materia medica, theory and practice, surgery and hygiene. To this has been added a physical examination. Our staff is composed of men who have been tried and found successful in their chosen profession; they have given to the work the requisite time and study which it demanded. And will you believe that their training has been for naught? That those who have studied and prepared themselves for this emergency have failed? To believe this is to be unreasonable and disloyal to our profession. The volunteer surgeon who was experienced in military medicine before the war, who was earnest in his calling, could not fail to do good work when summoned to active service.

Considering the fact that the present generation of medical officers has seen no active service, that the large volunteer army was raised at such short notice, it is not surprising that there was something lacking at its management.

The total number of deaths reported in our army, including regulars and volunteers, from May 1st, 1898, to April 30th, 1899, is 6 406. Of these 5,438 died of disease, and 968 were killed in battle or died of wounds, injuries or accidents. This statement makes a great impression as to the danger of disease rather than of bullets; but it is only fair to consider that an army of nearly a quarter of a million of men was exposed to disease for twelve months, where only a small portion of this army was exposed to bullets for a few months. However, considering this, it shows that the prevention of disease is a very important consideration in dealing with the health and effectiveness of an army. Had the entire army been engaged in active warfare, of course the percentage of deaths from wounds would have been much greater.

Petty bickerings between regular and volunteer surgeons, trying to shift responsibility from one to the other, only tends to lower both in the eyes of their fellow practitioners and the laity. Let them come together even more closely than formerly. Let them work together for the public good and remember above all things that they are members of the same profession. To say that regular army surgeons are not bright and intelligent physicians as a class is unreasonable. The examination that they pass for admission to the medical corps is sufficient to guarantee

this; to say that volunteers are ignorant and inexperienced is to belittle the whole profession and degrade it in the eyes of the people. They both are lacking in some qualifications to make the best type of medical officers; many of the volunteers are lacking in military medicine, particularly as regards red tape, etc., and the regular in experience in general medicine and surgery. The combination of the regular and volunteer would make the ideal medical officer. If the regular profits by his experience in this war, and the volunteer by his, and they work together harmoniously in the future, the question of good army medical service will be solved. Let us not give way to personal feelings, criticising physicians who have done the best they could under the circumstances, and who have perhaps done better than we could under the same conditions. Let us note our imperfections and try to improve the service for those who succeed us. Contributions furnished by experience will be a great aid to our successors. Exaggerated and sensational accounts of mismanagement do no good.

Some of the important improvements in our State service the past five years are as follow:

(1) Physical examination of recruits; at first voluntary and now made mandatory.

(2) Ration to be used at camp. Something after the pattern of army ration, but modified for adaptation to State service.

(3) School for medical officers. One session annually.

(4) Company bearers; four privates in each company specially trained in emergency and first-aid work.

(5) System of red tape patterned after regular army, but modified for State service.

I have merely touched upon certain suggestions which could well bear elaboration, but time and space forbid.

The following is a brief *résumé* of the suggestions offered to improve the efficiency of the army medical service. Some of them have been practically adopted by the Massachusetts Volunteer Militia, and it is hoped will be adopted by the entire National Guard:

(1) That professorships of military medicine be established in every reputable medical college.

(2) That until such time as professorships are established, the State provide a course on required subjects.

(3) That physical examination of officers and men be made mandatory.

(4) That troops at State encampments conform as nearly as possible to duties required in service on the field.

(5) That every medical officer receive commission. (This pertains to contract surgeons.)

(6) That one or more men in every company be detailed for regular instructions in ambulance corps, to prevent possibility in the future of the country losing the service of men especially trained for this service.

(7) That one medical officer be selected in each regiment or brigade for his surgical ability.

(8) That a corps of trained female nurses be organized in every State.

(9) That divisional hospitals, in the broad sense, be abolished, and that small brigade and divisional hospitals be established for special cases, such as surgical and contagious.

(10) That the volunteers follow, as closely as practicable, the regular army, so that when called into service together the two branches may work in harmony.

(11) In addition to the present instruction in "first aid," a course in prevention of contagious diseases, etc., be given.

(12) That a reserve staff of medical officers be formed in each State; said staff to be composed of ex-members of the medical department of the National Guard.

Clinical Department.

UNUSUAL DIASTOLIC MURMUR, WITH AUTOPSY.

BY RICHARD H. EDES, M.D.,
District Physician, Boston Dispensary,
AND
RICHARD M. PEARCE, M.D.,
Instructor in Pathology, Harvard Medical School.

THE following case seems worthy of record as helping to throw light on the causation and character of aortic murmurs, as well as for the other uncommon pathological conditions present.

The patient was a business man of active life, married, fifty years old, short and rather stout. No alcoholic or venereal history. Sciatica about five years, and a ruptured varicose vein about three years previously, during which sickness his physician said nothing to him or his family about the existence of heart trouble. About a year previously he lost most of his sleep for a few nights on account of pains resembling muscular rheumatism in his right shoulder, arm and forearm, but these practically all disappeared and did not return.

On February 18, 1899, he realized that something serious was the matter with him, having had a very restless and uncomfortable night, and complaining also of a "scraping" in his chest. This he said he had felt for about six months, but had thought to be only bronchitis! Some weeks previously he had had an attack of dyspnea after climbing stairs, but had soon recovered; and again, during the heavy snowstorm on February 13th, he had nearly collapsed between the train and his house, one-quarter mile, and had been feeling rather poorly since, although going actively about. His breathing on the nights of February 17th and 18th, as described by his wife, was Cheyne-Stokes.

A hasty examination gave a loud "scraping" murmur and thrill at the base of the heart, seeming systolic at first, as it was accompanied by a heave in the apex region, although by no definite apex beat which could be felt.

Further study developed the following picture: The apex beat could be felt very feebly at times in the sixth interspace, one inch outside the nipple in the dorsal position, and in the left side position quite distinctly a trifle further out. The heave was diastolic, very marked, and at times a distinct diastolic impulse, alternating with the true apex beat and with the carotid pulse, could be felt in the fourth and fifth interspaces inside the nipple. The heart dulness was enlarged, corresponding to the position of the apex, and the lower sternum was duller than normal. Later the lower sternum became quite flat to percussion and dulness extended about one-half inch to the right.

The liver was slightly enlarged. Two murmurs, a systolic and a diastolic, were heard all over the heart area; the systolic blowing, slight at the apex (where a slight but sharp first sound was heard), very distinct at the base, louder in the first right interspace, and loudest just above the inner end of the clavicle, where it became louder than the diastolic murmur and was accompanied by a systolic thrill and an impulse much more marked than above the left clavicle. There was no especially strong pulsation in the suprasternal notch. The diastolic murmur was heard all over the chest, loudest at the second right interspace, and could be heard without the stethoscope three or four feet away from the patient. It was accompanied by a powerful diastolic thrill felt all over the upper front chest. The character was best described as "scraping," although at times it was almost musical. It never intermitted or very markedly changed in character or intensity. The pulse, averaging about 92, was a fairly marked water-hammer, fairly strong, with an occasional occurrence of *pulsus intercidens*. A sphygmographic tracing showed the same characters, with so sharp a rise as to make any marked degree of stenosis very improbable. There was no marked arteriosclerosis of the brachials, radials or temporals.

The course of the disease was steadily but slowly downward, with a much congested liver, edema of legs, distressing attacks of orthopnea at times, congestion of veins of neck, and gradually rising average rate of pulse. About one month before death, which was on May 21st, the right radial pulse became distinctly weaker than the left and remained so, and about this time a dulness not detected before was made out, involving the upper sternum and a bit of the first interspace to the right. A slight hoarseness on March 11th, lasting about a week, seemed to be of inflammatory origin, as the temperature was slightly elevated on the first day. The Cheyne-Stokes breathing became more frequent but not constant, and the death was one of exhaustion and gradual failure. There was practically no pain at any time.

The autopsy showed the following conditions: There was marked passive congestion of liver, spleen and kidneys; moderate hydroperitoneum, hydrothorax and hydropericardium; arterio-sclerosis was not general. The heart was moderately hypertrophied (415 grammes), with quite an amount of epicardial fat, the left ventricle and left auricle considerably dilated, and the heart muscle showed marked fatty degeneration. The coronary arteries showed no changes, except just at the beginning of the left, where there were one or two yellowish non-calcareous patches; these did not seem of sufficient importance to cause the failure to compensate. The aortic valves were distinctly but not extremely incompetent, the circumference being nearly normal (8.4 centimetres) and the leakage being due to a shortening of the anterior cusp. Just above the junction of the anterior and left posterior cusps was an aneurismal pouch 1.2 by 2 centimetres in diameter and 1.6 centimetres deep, the edges slightly overhanging, containing no thrombi. The orifice of this cavity was in contact with the anterior cusp of the valve, which was somewhat shortened thereby, giving rise to the incompetence just mentioned. At the junction of the anterior and left posterior cusps there was a small area of subendocardial hemorrhage. The bottom of the aneurism was opposite the left auricle, the endocardium of which was thickened at this point over an area three centimetres in diameter. The aorta showed a dilatation of the arch and descending portions. This dilatation was most marked in the ascending and transverse portions of the arch and gradually diminished to a point opposite the second intercostal arteries. At a point four centimetres above the aortic valves the circumference of the aorta was 13.5 centimetres. Calcareous plates were very numerous and over some of them the intima had entirely disappeared, leaving small, roughened, blood-stained areas. There were also seen a few flattened areas, non-calcareous, but containing a soft yellowish material.

The orifice of the innominate artery measured two centimetres in diameter; one centimetre above this orifice was a sacculated dilatation 3.5 centimetres in diameter, to one side of which adhered a firm grayish-red thrombus. This aneurism extended up to the division into carotid and subclavian, which vessels were compressed by the thrombotic mass. The vessels, however, were pervious.

In the right auricle, occupying the auricular appendage and extending into the auricle proper, was an adherent mass five by three centimetres, grayish red on surface, on section showing a softened centre of yellowish, granular material. Right side of heart otherwise negative.

In regard to the interpretation of the clinical signs by the pathological findings, the weak right radial pulse was of course due to the innominate aneurism. The systolic murmur and thrill were probably also produced in this aneurism or possibly in the opening between it and the aorta. It will be noted that no aortic stenosis was present.

In regard to the dulness of the upper sternum and first right interspace detected about a month before death, it would seem as if some change must have taken place during the course of the disease, consisting either of an enlargement of the innominate aneurism, of increased congestion of the innominate veins, of more careful percussion, or perhaps of all three.

Now as to the most marked feature of the case, the unusually loud and rough diastolic murmur, was it caused by the aortic aneurism alone, by the incompetent valve alone, or by the combined effects of the two? To the first hypothesis is opposed the great difficulty of explaining why the effect of the systole and diastole should be so different. As to the second, loud diastolic murmurs are mentioned by a number of authors (Bramwell, Gibson, Broadbent, Steele, and others), and a number of cases are on record. In those cases, however, which do not have a special cause for the loud murmur, such as a torn valve flap, etc., the murmur is generally musical, or intermittent, or both. All, or nearly all such cases, show extensive arterio-sclerosis, as did this case in the aorta and some of the large vessels. It would seem then reasonable to expect to find in each case of rough diastolic murmur a special cause over and above a leaky valve. In this case the mode of production of the murmur may be imagined in this way, that the regurgitant blood current, instead of flowing smoothly through the valves, causing fine vibrations and a soft murmur, formed a whirlpool in the small aneurism, becoming turbulent just at its passage through the valves, and thus giving rise to coarse vibrations and a loud, rough murmur. It is probable that the dilated and sclerotic condition of the aorta had some influence on the character of the murmur. In this connection it is interesting to note that in 22

cases of aneurism of the sinuses of Valsalva,[1] a location slightly nearer the semilunar valve flaps than in our case, no instance of rough, diastolic murmur occurred.

Medical Progress.

REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D.

THE FINER CELL CHANGES IN MENTAL PATHOLOGY.

Angiolella[1] has made a careful review of the finer changes in the nerve cell in various forms of mental disease. He maintains that the basis of a normal and pathologico-anatomical psychology is but just beginning to appear on the distant horizon and that the secret of life and its various functions must be sought in the study of the single cell elements, and their chemical constitution. The change which this constitution undergoes in the various functional states and pathological operations is to be applied to the physiology of the nervous system and is beginning to give results. The method of Golgi has permitted us to realize immense progress in our knowledge of the normal morphology of the nerve cell and to recognize some slighter pathological changes, such as the atrophy and hypertrophy of the protoplasmic processes and alteration in the shape of the cell body; but Nissl's method has permitted us to recognize the intimate changes in the cell. Among these, the most important are the various changes of chromatolysis, that is, the dissolution and gradual disappearance of the chromatic substance of the cell, which is one of the most frequent and best recognized alterations in various pathological conditions. In all degenerative processes this substance is the first to feel the injury of disturbed nutrition and to be altered by it. Since it is known that organic molecules of the highest and most complex chemical constitution and the highest biological signification are the most susceptible to injurious influences and the first to feel their effects, it is fair to suppose that this chromatic substance, Nissl's bodies, is of the highest importance in the constitution of the cell body as producing, accumulating or directing nervous energy. Along with the dissolution of the chromatic substance go alterations in the fibrillary reticulum, with alterations in the shape of the cell body, dislocation of the nucleus and complete destruction of the cell.

Researches upon cases of mental disease are as yet few, and the changes thus far have been found only in general paralysis, some cases of terminal dementia, epilepsy, pellagra and acute delirium. Cases of mania, melancholia and even of paranoia are apt to die either in a stage of terminal dementia or of some intercurrent disease. Experimental research, however, has given us important aid in the study, especially by investigations on poisoning of animals by alcohol and lead, auto-intoxication, infection, exhaustion, and the like. In all these conditions we find degenerative changes of the nervous elements, and the logical deduction is that similar changes may occur in man under the same morbid influences and that these changes may have relation to the functional disturbances which are seen in these conditions. The excitement or the hallucinations of the alcoholic patient, perhaps the paranoia and the pseudo-general paralysis of chronic alcoholism, the delirium of typhoid and pneumonia, the nervous and mental disturbances of uremia and diseases from auto-intoxication, and the psychoses from exhaustion, deprivation of nutritive material or excessive nervous worry and defective repair may to-day be put in direct dependence upon the nutritive and morphological alterations of the nerve cell, and especially the cerebral nerve cell. We are also led to believe that ordinary mania, melancholia, sensory delirium, and the epileptic attack may be occasioned, in predisposed subjects, by the action of toxic products upon the system and the nervous elements; so that alcoholic excitement, for example, may have the same pathogenic mechanism as the ordinary maniacal attack and may differ from it only in the nature of the poisonous substance.

The conception of a psychosis without a corresponding material change may fairly be banished from our knowledge. We do not yet know why, under the action of the same or different poisons, the forms of mental disturbance are so varied, while the cell alterations are nearly uniform. We are still ignorant if the various methods of alteration and degeneration have a special significance in producing the varied forms of functional disturbance or if the production of morbid phenomena varies in relation to the prevalence of one or another form of degenerative process with the different localization of the lesion or with the individual temperament. We are still ignorant if the diversity of temperament varies with the different composition of the cell element or the varying behavior of the elements to the same stimuli.

ACUTE PSYCHOSIS IN COPROSTASIS.

Sölder[2] reports six cases presenting the symptoms of acute delirium associated with intestinal disease. A previously healthy individual is suddenly or rapidly attacked with symptoms of violent mental disturbance, without reasonable cause, and after some indifferent prodromes, lasting a few days. The mental trouble began with confusion, a loquaciousness, a rapid flow of ideas, an expansive and excited emotional condition, soon followed by a clouding of consciousness and agitation, which rapidly sunk to symptoms of motor irritation of the simplest sort, grimacing and various automatic movements. The speech became incoherent and there was a tendency to verbigeration; there was sleeplessness and failure of nutrition; the temperature was not elevated. The physical examination was negative. Constipation existed in all the cases; death followed in ten to fourteen days. The autopsy showed hyperemia and edema of the brain, marked congestion of the lungs, parenchymatous degeneration of the kidneys, heart and liver, and marked coprostasis in the large intestine, with alterations in the intestinal mucous membrane. The history showed that the constipation preceded the mental disturbance, which was regarded as a result of it; and the author concludes that an acute psychosis may be the result of coprostasis and may run a course similar or identical to that of acute delirium, causing death by weakness of the heart in one to two weeks. One case recovered after complete emptying of the intestine. The author reviews the theories as to the relation between the intes-

[1] Reported by Cattell and Steele: Pathological Society, Philadelphia, vol xviii, 1898, p. 203, et seq.

[1] Annali di Nevrologia vol xvi., page 362.

[2] Jahrbücher f. Psych, vol. xvii. p. 174.

tinal trouble and the mental disturbance. The old theory of hyperemia of the brain is not regarded as a sufficient explanation, although hyperemia is usually present. We know too little of the symptoms due to hyperemia, and in ordinary hyperemia, due to disturbances of the circulation, acute delirium does not occur. The second theory is that the trouble is due to an invasion by some form of bacteria, and, in a few cases, bacteria have actually been found in the blood, the urine, and even in the cerebro-spinal fluid. The third theory, to which the author is disposed to ascribe the greater weight, is that of auto-intoxication from the intestine, although he failed to find acetone in the urine in any case and an excess of indican in but one.

Galante [3] reports two cases, with the following conclusions, from the work based upon the researches of Bianchi and Piccinino. Among the psychopathological forms which are confused with acute delirium is one which may be called acute bacillary delirium, which is distinguished from the rest clinically by a greater intensity of the phenomena, by a dynamic phase, which rapidly succeeds the period of excitement, by the very short course, and by the fatal termination; bacteriologically by the presence in the blood and nerve centres of a special bacillus. There are forms of acute sensory delirium, with a febrile course, where the delirium is due to the fever and not to the action of a bacillus. The true bacillary delirium must be regarded as a grave infectious disease, and cannot be certainly recognized without an examination of the blood. Other forms of acute delirium and grave mania may show micro-organisms in the blood, but in smaller quantities and not of the specific type. Galante therefore concludes that these cases of coprostasis are due to the intoxication rather than to any micro-organism from the intestine, which conclusion is strengthened by the fact that in one case, after thorough intestinal evacuation, the symptoms of delirium disappeared.

Ceni and Ferrari [4] have held that the various micro-organisms found in acute delirium represent only a secondary infection, chiefly of intestinal origin and cannot have a definite etiological value. They have studied the blood in 18 cases of mental disturbance of various sorts presenting severe symptoms. In seven cases they obtained positive results in their bacteriological researches. Of these, one was in the status epilepticus, five were cases of severe mania, and one was in the maniacal stage of general paralysis. In all of these seven cases there was considerable elevation of temperature. In each of the cases where there were positive results a pure culture of a micro-organism, which remained constant in the individual, could be isolated. In five cases streptococci were found; in the other two varieties staphylococci were found. From these researches they conclude that severe maniacal excitement, with a clinical aspect analogous to acute delirium, and also marked mental confusion as observed in the status epilepticus, are attended with micro-organisms in the blood only when accompanied by fever. The presence of fever and the course and termination of the disease have no relation to the form of micro-organism but only to the degree of its virulence.

RETROGRADE AMNESIA.

Paul [5] reports a case of retrograde amnesia coming on after puerperal eclampsia, which began on the 14th of December, the patient remaining unconscious for six days; after that there was a condition of confusion, with hallucinations for a considerable period and an hysterical condition which lasted for a number of months. With this there was a marked loss of memory extending backwards to the 1st of October. She knew nothing of the eclampsia or of her hallucinations; later on the amnesia extended backwards to the month of May. The former amnesia was regarded as of eclampsic origin and the latter of hysterical. After a careful study of reported cases, he concludes that the symptom of retrograde amnesia is comparatively common as the result of an hysterical attack, and it may occur in epilepsy and puerperal eclampsia and also after injuries to the skull and in those restored to life after hanging. It may also be due to poisoning by carbonic oxide or alcohol. In all these conditions there is the one common fact that a change of consciousness precedes the amnesia; an alteration of consciousness, without a loss, in hysteria, and a varying loss of consciousness in the other conditions. The cause of the change of consciousness in hysteria is usually some emotional disturbance. In the loss of consciousness in epilepsy and eclampsia, and in hanging, the cause is probably due to a change in the circulation. In injuries to the head it has been referred to the concussion of the brain, and in the poisoning to the amount of the poison. We are wholly ignorant of the nature of the process or of the nature of the occurrence of this symptom.

EXHIBITIONISM.

Seiffer [6] reports seven cases from Hitzig's clinic and has collected 75 other cases in men and 11 in women. Of the men, 18 were epileptics, 17 dements, 13 degenerates, eight neurasthenic and eight alcoholic. In only two of the epileptics was any consciousness of their acts present. It is probably more common among the insane than the statistics show, because most of them are confined in an asylum, so that their acts are not so prominent and do not lead to public scandal. In the reported cases there is a striking similarity in the acts. It is found in all classes of society and at all ages, although very rarely in women. In the majority of cases there is a disturbance in the mental condition which renders them irresponsible.

TUBE FEEDING AND SCURVY.

Klein [7] has made a careful study of the relations between long-continued tube feeding and scurvy, reporting three cases, two of which terminated fatally, in which scurvy developed during long-continued tube feeding; in the third case, the scurvy disappeared after giving meat and lemon juice. He concludes that the special cause of scurvy is to be found in the form of nourishment. The other etiological factors play at most a secondary part. In his own cases it seemed extremely impossible that the invasion of micro-organisms led to the outbreak of the disease, but a secondary invasion is almost certain to occur. The active prophylaxis of scurvy is to be found in the sort of food given, and the form of treatment must be chiefly dietetic; fresh meat, fresh vegetables and lemon juice are to be regarded as the active agents in restoring health. In asylums, not only with patients who re-

[7] Monats. f. Psych., April, 1898.

fuse food absolutely and must be fed by the tube, but also in patients who are insufficiently nourished, or who, on account of their delusions, limit themselves to certain classes of food, we must always consider the danger of scurvy and guard against it by appropriate diet.

ACUTE PERIODIC PARANOIA.

Giannelli[8] considers the question of an acute hallucinatory periodic paranoia. Acute paranoia must represent an abbreviated form of chronic paranoia. It must be a systematized delusional state, beginning more or less suddenly and accompanied, or not, by hallucinations. When there is no bond between the delusional ideas there is no paranoia. The exaggeration of personality is not sufficient to warrant us in affirming the existence of an acute paranoia, which must be clearly separated from mental confusion.

Giannelli is unwilling to accept the position of Ziehen, who seems to think that it is sufficient to formulate a diagnosis of paranoia if we can confirm the co-existence of sensory hallucinatory disturbances and delusions. The symptomatology alone is not sufficient for classification. We must keep in mind the association of symptoms and their succession in order to differentiate those morbid forms which should be kept distinct notwithstanding many points of contact. The existence of an acute systematized insanity of a periodic course does not seem to him proven by the cases thus far reported.

GENERAL PARALYSIS.

Mendel[9] raises the question whether in the last ten years the clinical picture of general paralysis has undergone any changes. Calmeil in 1826 claimed that melancholic conditions were extremely rare, but in 1859 he asserted that the melancholy form was almost as common as the delusions of grandeur. Mendel himself, in the thirty years in which he has studied general paralysis, has been struck especially by the fact that the typical form of general paralysis has become much less common than the demented form. In the older observations the typical form was seen in more than half the cases, and Mendel himself in 1880 had found it 55 times in 180 cases. In the last eight years, however, it has been found only 24 times in 194 cases. The delusions of grandeur, even in the typical form, are by no means so excessive as they formerly were. In 1880 Mendel had noted the demented form in 37 cases, whereas in the last eight years it had been noted in 70. The frequency of the demented form, moreover, Mendel thinks, would be still more evident if we were to take into consideration the no small number of these cases who, on account of their quiet condition, are not obliged to be sent to an asylum and are seen only in private practice or in general clinics. This change can hardly be due to improved methods of diagnosis, since the time has been so short. A second change, which of late years has been striking, is the comparatively frequent occurrence of considerable remissions, although accurate statistics are lacking to prove this point. They occur, however, in a number of cases which have presented marked mental and physical symptoms and also in the early stages, and may last for a year or more. The course, in general, seems somewhat milder, but, on the other hand, the disease is much more frequent and is noted more often in women. In 1859 Neumann claimed that general paralysis occurred only in men, but at the present time one-fifth of the cases are found to be in women. The number of cases in children also shows a marked increase, and in children the disease is about as frequent in girls as in boys. The cause of the increase is attributed to the increase in the amount of syphilis and in the increased struggle for existence; and Mendel refers the increase of the disease in women to their increasing participation in the social struggle and the so-called "emancipation" of the sex. The cause of the change in form is obscure. He does not regard it as due in any way to previous antisyphilitic treatment, since there seems no change in the cases which have been thoroughly treated and those which have not; nor can it be explained by an earlier commitment to an asylum and better treatment; neither does he consider that our brains in the last twenty-five years have become less capable of resistance and are no longer capable of maniacal exaltation, and that the change therefore is not due to an increasing degeneracy. It may possibly, however, be due to some change in the syphilitic poison.

(To be continued.)

Reports of Societies.

AMERICAN ORTHOPEDIC ASSOCIATION.

THIRTEENTH ANNUAL MEETING, HELD IN NEW YORK, MAY 31, JUNE 1 AND 2, 1899.

(Concluded from No. 6, p. 142.)

THE KYPHOTONE — A MACHINE FOR THE FORCIBLE CORRECTION OF THE DEFORMITY OF POTT'S DISEASE.

DR. R. TUNSTALL TAYLOR, of Baltimore, exhibited this instrument, which was intended to make traction backward on the trunk and spine during the application of the plaster jacket. The advantages claimed for it were: (1) The spine was fixed in the most advantageous position; (2) the rapidity and ease with which the jacket could be applied; (3) its applicability to cases of mid-dorsal, lower dorsal and lumbar caries; (4) the removal of the superincumbent weight from the diseased articular processes, and (5) the inexpensiveness of the apparatus.

SOME NEW TRACTION APPARATUS.

Dr. Taylor also exhibited and described a new traction apparatus, characterized by simplicity of construction and provision for sterilization and securing the highest degree of cleanliness. His folding steel apparatus for making extension with weight and pulley and inclined plane was especially worthy of commendation.

A SUMMER PLASTER-OF-PARIS JACKET.

DR. TAYLOR and DR. S. H. MCKIM also exhibited a method of making plaster jackets by means of figure-of-eight bandages, so as to leave a considerable area anteriorly exposed.

CELLULOID JACKETS.

DR. AUGUSTUS THORNDIKE, of Boston, reported that although the celluloid bandages that he had de-

scribed last year had worked well at first, he had subsequently been much disappointed with the process.

DRS. SHERMAN and TOWNSEND said that they had a like experience with the working of celluloid.

DR. R. H. SAYRE said that he had learned that it was better to work with sheets of celluloid, placing them on a wire tray in a shallow box, and exposing them for three hours to the vapor of acetone. A thorough and uniform action of the acetone was best secured by soaking sheets of blotting-paper in acetone and laying them under the tray supporting the celluloid sheets. After the sheets had been sufficiently softened, they were to be applied to the mould and fastened with either muslin or rubber bandages. In this way a beautiful corset could be made, but it was so intolerably hot that the patient would refuse to wear it, and this too, even after holes had been provided for ventilation.

DR. E. G. BRACKETT, of Boston, said that his experience had been that if the celluloid were taken off the mould before the expiration of two or three weeks it would surely curl up.

FURTHER OBSERVATIONS ON THE TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

DR. ROYAL WHITMAN, of New York, read this paper and exhibited quite a large number of patients that had been treated by him. He had operated 32 times on 21 patients by the bloodless method, and all had been treated more than two years. Of the 19 open operations that he had done, 15 had been in the present year. There had been no operative infection of the wound, and no deaths. Under proper conditions he considered the open operation to be free from danger and easy of performance. He had treated in all 41 cases, 27 of them by the functional method of Lorenz. On seven patients both methods had been used. Of the 14 unilateral cases, nine had been treated by forcible correction, and when this had proved unsuccessful had been supplemented by the open operation. He had had three perfect cures by the bloodless method, and had obtained an excellent result by this method in a girl of seven years, although it was ordinarily not very successful in these older children.

CONGENITAL DISLOCATION OF THE HIP.

DR. T. HALSTEAD MYERS, of New York, exhibited a child of three years upon whom he had successfully operated in 1895 by the bloodless method. He had since that time treated 15 other cases in the same way. Five of these would probably yield a perfect ultimate result; in three the treatment had failed.

DR. RIDLON said he could not agree with Dr. Whitman concerning the great disability observed in cases of congenital dislocation of the hip, as the adult patients whom he had seen had been able to walk fairly well, though not gracefully. In the majority of instances they could walk fairly long distances with comparative comfort.

DR. B. E. MCKENZIE said that he had employed the bloodless method in two, and the open operation in one case. He had operated upon a child of nine years, and there was every prospect of a good result ultimately.

DR. L. A. WEIGEL said that radiographs of these cases seemed to indicate that there was an arrest of development, not only of the femur, but of the whole side of the pelvis.

DR. H. A. WILSON said that it was not at all uncommon for orthopedic surgeons to meet with adults in whom the functional condition was good, and in view of the mortality and the anchylosis attendant upon the open operation, it was well to counsel conservatism in this class of cases.

DR. SHERMAN said that these children were usually brought to the surgeon not because of disability or pain, but because of the ungraceful gait. Dr. Whitman's results were infinitely better than anything that had been shown him in Vienna by Lorenz four years ago, and were encouraging to the highest degree.

DR. WHITMAN reiterated the statement that these patients did suffer pain and presented a relative disability. Intermittent force in young subjects would best bring down the head of the bone.

SYMMETRICAL ENLARGEMENT OF BOTH LEGS FROM POSSIBLE LYMPHANGITIS.

DR. S. KETCH, of New York, presented a patient exhibiting this condition, which he attributed to the occlusion of the deep lymphatics.

DR. W. R. TOWNSEND exhibited a photograph of a case in which there was a similar enlargement, although confined to one side.

OSTEOMA OF THE FEMUR.

DR. KETCH exhibited a radiograph of such a case.

OBSCURE INJURY TO ELBOW.

DR. WEIGEL presented a young woman who had injured her elbow in a bicycle accident. He had at first treated her by rest of the joint, and she had done well. She had then come under the care of a physician who had insisted that there was a fracture, and had proceeded to refracture it under an anesthetic, with the very natural result of making the condition worse. A radiograph taken after the accident showed plainly that there had been no fracture.

UNUSUAL DEFORMITY FOLLOWING OPERATION FOR KNOCK-KNEE.

DR. W. R. TOWNSEND presented a girl of thirteen years having a dreadful distortion of her limbs following an osteotomy which another surgeon had done on her in childhood. This surgeon admitted that after the osteotomy the wound had become septic. A radiograph showed that the lower end of the femur had been rotated out at a right angle.

A CASE FOR MUSCLE TRANSPLANTATION.

DR. V. B. GIBNEY exhibited a boy of six years having an extreme recurvation. He intended to try the effect of transplantation of muscle.

ENLARGEMENT OF TIBIAL TUBERCLES.

DR. HENRY LING TAYLOR, of New York, presented two cases of this kind, one a boy of twelve, and the other a boy of sixteen years. In the first case there had been no assignable cause; in the second there had been a trauma. In both the periostitis had been relieved by the topical use of iodine.

Several of those present reported similar cases, occurring, for the most part, in athletes.

PARTIAL LUXATION OF THE HUMERUS FOLLOWING ANTERIOR POLIOMYELITIS.

DR. J. H. WATERMAN, of New York, presented this case. The patient was a youth who had probably had an anterior poliomyelitis of the fifth cervical

segment in infancy. Irritation of the pectoralis major produced dislocation of the shoulder.

SPASMODIC TORTICOLLIS.

DR. CHARLES E. THOMPSON, of Scranton, present by invitation, reported this case, and exhibited both this patient and another whom he had cured of the same affection. In both instances several sections of nerves had been demanded before relief had been afforded.

CASES OF TUBERCULAR AND PURULENT ABSCESSES OF JOINTS TREATED WITH CARBOLIC ACID.

DR. A. M. PHELPS, of New York, made some remarks on his work in this line. The essential feature of the treatment was the utilization of Dr. Seneca D. Powell's discovery that alcohol was a perfect antidote for carbolic acid. The carbolic acid was injected into the cavity, allowed to remain for two minutes, and then the cavity washed out first with alcohol, and lastly with sterile water. In every case so treated, except those in which drainage-tubes had been used, primary union had occurred. Moreover the patients so treated had been discharged in from two to five weeks, instead of remaining several months, as they were compelled to do when treated by the more usual methods. Dr. Phelps said that the manner in which the alcohol acted was not yet known, but he suspected that it formed with the albuminates in the mucous layer of the skin a harmless compound, which was absorbed and acted as a powerful bactericide.

DR. R. H. SAYRE said that he was reminded of Callender's work some years ago, with carbolic-acid injected into joints. The method had been abandoned because of the numerous fatalities from carbolic acid poisoning. If this danger could be eliminated, the method just described by Dr. Phelps should have a great future.

MULTIPLE DEFORMITIES OF THE EXTREMITIES.

DR. GEORGE R. ELLIOTT, of New York, reported such a case occurring in a child of eleven years, and apparently the result of either intra-uterine traumatism, or, more probably, primitive changes in the nervous system.

DR. EDWARD D. FISHER, of New York, said that this was apparently one of those rare instances of diffuse myelitis occurring during intra-uterine life.

DR. S. B. ONUFF, of New York, said that the fact that the changes in this case were spread over the whole anterior horns seemed to argue in favor of their being primary rather than secondary.

POINTERS ON THE LEATHER SPLINT.

DR. A. J. STEELE, of St. Louis, under this caption described his method of making leather corsets. He said that the ideal leather for this purpose was that which had been only half tanned, but, of course, it could not often be procured. After having softened the leather by soaking in water, he wraps it around the cast, and then by means of a mechanical device binds it on very tightly with stout cord. It is then baked in an oven at a temperature of 180° or 190° F. for two or three days.

DR. MCKENZIE remarked that he had found rawhide corsets very useful and exceedingly durable; the chief drawback was that they required two or three weeks to dry.

THIRD DAY.

NEW INSTRUMENTS — AN OSTEOCLAST; A BRACE FOR FLAT-FOOT AND PARALYSIS; A BRACE FOR FORCIBLE EXTENSION AND FLEXION OF THE ELBOW.

DR. G. G. DAVIS, of Philadelphia, presented these instruments. The osteoclast was designed for breaking the bone accurately after it had been partially divided by the osteotome. The elbow brace was intended, like the Stromeyer apparatus, to produce forced extension and flexion, and was an improvement on that apparatus in that by a shifting fulcrum a greatly increased degree of flexion could be obtained.

A NEW HEAD SUPPORT.

DR. S. L. MCCURDY, of Pittsburg, exhibited an X-shaped frame, made of heavy steel wire, which he devised as a head rest for cases of cervical caries. Pads were placed at the four points of support, that is, the occiput, chin, sternum and back below the vertebra prominens. Dr. McCurdy also exhibited a new additional chin support.

POCKET GONIOMETER.

DR. W. E. WIRT showed a goniometer, having telescopic legs, which he carried around in his pocket for a number of years, and had found very useful.

Dr. Wirt also exhibited a

KNEE BRACE FOR CORRECTING DEFORMITY.

It was a simple and cheap instrument which pushed the head of the bone forward while making extension.

THE CORRECTION OF FLAT-FOOT.

DR. H. A. WILSON exhibited a simple instrument that he had devised for correcting flat-foot by means of force applied by a screw in appropriate directions.

DR. WEIGEL saw no advantage in Dr. Davis' elbow brace over the simpler one in which the same object was accomplished by levers placed at the side of the arm.

DR. SHERMAN thought Dr. McCurdy's head-support would allow of too great lateral play.

DR. WHITMAN advised that the correction of cases of long-standing flat-foot should be accomplished by holding the foot between the knees and subjecting it to extreme abduction.

FRACTURE OF FEMUR WITHOUT THE USUAL SIGNS.

DR. C. L. STARR, of Toronto, reported a case occurring in a child of three years, in which, although there had been a fracture at a point just beyond the junction of the head and neck of the femur, as demonstrated at autopsy, there had been no pain or the usual signs, and a positive history of limping for only two weeks previously. After the post-mortem examination, the parents recalled the fact that only six weeks before the limp had developed the child had fallen from a high chair.

POSITION SYMPTOMS IN JOINT DISEASE.

DR. HARRY M. SHERMAN, of San Francisco, presented in this paper an elaborate study of these symptoms and of the various theories propounded to explain the positions assumed. He stated that so far as the theories of Hilton and of Phelps were based on one group of muscles, they must be laid aside. In tuberculosis of a joint some of the osseous trabeculæ are destroyed, and a spot of bony weakness produced, a fact

which seemed to be appreciated by the person involuntarily shrinking from putting work on this spot.

SOME SALIENT POINTS IN THE TREATMENT OF HIP DISEASE.

Dr. B. E. McKenzie read a paper with this title. In his opinion no other apparatus had been so successful as the brace of Mr. Thomas and its modifications. Care should be taken to secure sufficient bending at the knee. The tendency in the later stages to abduction could be counteracted and the muscular spasm overcome by the expedient of making traction on the side opposite to the one affected. He had abandoned the idea that the splint should also act as a crutch. Constitutional treatment, as in other tuberculous affections, was indicated. After excision a perfect recovery could never occur; complete restoration of function was sometimes possible after proper mechanical and constitutional treatment.

THE CONSERVATIVE SURGICAL TREATMENT OF TUBERCULOUS DISEASES OF THE JOINTS.

Dr. C. L. Starr, of Toronto, presented, by invitation, this paper. He advised incising and curetting tuberculous cavities, swabbing with chloride of zinc or with carbolic acid, injecting iodoform emulsion and finally packing with iodoform gauze.

ADDITIONAL VIEWS ON THE TREATMENT OF HIP DISEASE.

Dr. A. B. Judson, of New York, presented a paper with this title. His method of treatment consisted essentially in educating the patient to the habitual observance of the normal rhythm of locomotion. As a result of this training, the limb which had been abducted gave up some of its abduction in order to reach the ground more conveniently, with the result that there was a decrease in the apparent shortening.

Dr. Weigel said that if the focus of disease could be definitely located — and it could be at present with the aid of the x-ray — the treatment advocated by Dr. Starr should be successful.

Dr. Judson said that he could not agree with Dr. Sherman that muscular action could be entirely eliminated, for it was this, in his opinion, which caused fixation.

Dr. Steele said that he, too, was not yet prepared to throw aside muscular spasm and the valuable experience of the past with reference to the action of traction.

Dr. Whitman thought Dr. Sherman should have paid more attention to the part played by habitual use in the final production of deformities, rather than limiting himself so closely to bone disease as an explanation of all these symptoms.

Dr. G. G. Davis said that he had tried the method of trephining the bone at the supposed site of the tubercular focus, and had found that it had apparently stopped the disease.

Dr. Judson was inclined to think that for a long time in hip disease it was inaccurate to speak of the joint as fixed.

Dr. Sherman said that when he had said that there was no muscular spasm *per se* he had meant that it did not originate in the muscle, as in the case of cramp. The muscles were implicated, but only as the servants of the bones and of the spinal cord. As at the beginning the sole lesion was in the bone, one must look to that lesion for the motive.

SOME CLINICAL FEATURES OF RHEUMATOID ARTHRITIS.

Drs. R. T. Taylor and S. H. McKim, of Baltimore, presented this paper. They asserted that this disease was usually bilateral, and rarely presented any abnormality in the bones or cartilages. A characteristic feature was the involvement of the cervical portion of the spinal cord.

OLD SUBCORACOID DISLOCATIONS OF THE HUMERUS.

Dr. Griffith, of Kansas City, said that he had found in operating on two such cases that even with a very long incision and prolonged and violent manipulation he had not been able to reduce the dislocation until the long head of the biceps had been severed. He had also discovered that when this had been done the replacement of the head of the bone was made quite easy by the use, as a lever, of a long and powerful periosteotome having one end sharply curved. The division of the biceps in this manner caused no subsequent trouble.

Dr. G. G. Davis said that in operating on a case of old subglenoid dislocation he had found it necessary to loosen nearly three-fourths of the attachment of the pectoralis major and divide the attachments of the supra- and infra-spinatus muscles, and finally the capsule around and below the head.

HEAT AS A THERAPEUTIC MEASURE.

Dr. S. L. McCurdy, of Pittsburg, read a paper with this title, in which he detailed some observations that he had made with a view to determining the temperature of the structures below the surface, and the effect of such heat on bacterial life. He found that the temperature of these deeper structures was practically unaffected.

Dr. Wirt said that the hot air acted chiefly on the circulation in the blood-vessels and in the lymphatics, and upon the nerves of the part.

SURGICAL INTERVENTION IN CASES OF SPASTIC PARALYSIS.

Dr. B. E. McKenzie, of Toronto, said that in the treatment of these cases he favored tenotomy of the abductors and abduction of the limb to an angle of 60° or 90°, and the retention of this position for several weeks. The results from this treatment, even in most forlorn cases, had been extremely gratifying.

Dr. S. Ketch said that he had reached about the same conclusions as had the reader of this paper. Until the time had arrived when the contracture had become less prominent it was not proper, in his opinion, to perform tenotomy. Mechanical appliances for these defective children were usually harmful.

Dr. Ridlon believed that all these children should be operated on when young because the irritation was thereby relieved and the mental condition often improved. He had obtained good results from the use of braces in such children.

Dr. Sherman said that he cut the tendons freely and separated the legs as widely as possible, and if they relapsed the operation was repeated.

Dr. Judson relied a great deal upon education in the treatment of these unfortunate cases, but used mechanical treatment where locomotion was interfered with.

Dr. N. B. Shaffer said that if these cases were carefully watched there would be found a time when

the spasticity would diminish, and he learned to defer treatment until this stage had been reached.

DR. E. H. BRADFORD, of Boston, said that while much could be accomplished by patient mechanical treatment, he confessed that the cure was much more rapid and thorough when tenotomy was done.

THE STATE CARE OF INDIGENT CRIPPLED CHILDREN.

DR. ARTHUR J. GILLETTE, of St. Paul, spoke of a new State hospital for the care of such children.

THE CAUSE OF FAILURE AFTER PHELPS'S OPERATION FOR CLUB-FOOT.

DR. DANIEL LA FERTÉ, of Detroit, present by invitation, read a paper with this title. He insisted that it was essential to open the mediotarsal joint, and, in severe cases, to divide the plantar ligament. After operation the usual methods for developing the muscles should be used, and they would be made easier if it were not necessary for the patient to wear any apparatus.

DR. MCKENZIE said that he had long been of the opinion that Phelps's operation proceeded on a wrong principle, and that the cutting of the tendo Achillis should be the finishing point instead of the point of beginning. Where the equinus could not be corrected it was because the astragalus could not be pushed in between the malleoli. In such cases it seemed to him wise to remove the astragalus.

DR. W. O. PLIMPTON said that the object of cutting the tendo Achillis first was to afford better leverage for the bringing down of the heel.

PROTHESIS, A BRANCH OF ORTHOPEDIC PRACTICE.

DR. A. B. JUDSON presented in this brief paper descriptions of several of the more important mechanical devices used by him in his work.

A PRELIMINARY REPORT OF A STUDY OF SHORTENING OF THE TIBIA IN CONNECTION WITH TUBERCULOUS DISEASE OF THE HIP.

DR. RUSSELL A. HIBBS, of New York, presented by invitation this paper. A study of forty-one cases had shown that the greatest shortening had occurred in the non-suppurative cases. He concluded, from his observations, that shortening of the tibia might be expected in a large percentage of cases of hip disease where it had lasted for one year.

The following officers were elected: President, Dr. Harry M. Sherman, of San Francisco; Vice-Presidents, Drs. R. Tunstall Taylor, of Baltimore, and A. R. Shands, of Washington, D.C.; Secretary, Dr. John Ridlon, of Chicago; Treasurer, Dr. E. G. Brackett, of Boston.

Recent Literature.

Wesen, Ursache und Behandlung der Zuckerkrankheit (*Diabetes Mellitus*). By DR. ALBERT LENNÉ, in Bad Neuenahr. Berlin: Verlag von S. Karger. 1898.

Diabetes mellitus is not only more often recognized at present than heretofore, but apparently the modern ways of living are increasing its frequency.[1] There is not a disease in which time spent in the study of the treatment of the case in hand brings so prompt a reward, and correspondingly few diseases which show so plainly a lack of proper attention. For all these reasons we welcome Dr. Lenné's book, which is an octavo of 152 pages.

In the first half of the work the writer discusses in two chapters the normal metabolism of the body and its modifications in diabetes. In two more chapters the symptoms, complications, causes and the prognosis, course and diagnosis are reviewed. The remaining half of the book, which is far and away the better part, is concerned with treatment. The author's experience embraces 352 cases, which is more than twice the number occurring in the Massachusetts General Hospital in seventy-four years. Though a physician in a bath resort (Neuenahr), Dr. Lenné studiously avoids bringing this to the foreground.

The discussion of diabetes contains little that is new, yet presents the recent work in an agreeable form. The book does not pretend to be exhaustive, and its scope is ample enough for the general practitioner. The chapter on treatment is so excellent that the reviewer regrets that it is not published in English. American doctors cannot too often have the basis of a rational diet in diabetes placed before them. "The first aim in the treatment of diabetes under all circumstances and in all cases must be to overcome the glycosuria . . . yet never at the cost of the patient's general condition." In a disease in which the abnormal course certain food-stuffs take is the striking feature the study of the diet becomes the principal factor. And Lenné commences at the beginning and in a clear exposition shows the relation of calories to kilos, and the nutritive values of the various classes of foods. Just as the carbohydrates must be limited, so must the albuminous food be curtailed. Prout, in 1820, called attention to this latter fact, which Bouchardat, Cantani, Naunyn, and, in this book, Lenné so strongly emphasize. Indeed Lenné bases his prognosis to a considerable degree on the amount of proteid food it is necessary to give the patient to maintain his body weight. The book is very helpful in the suggestions it contains for ways in which fats may be inserted into the dietary.

Treatment is commenced after an examination of the twenty-four hours' amount of the urine of the patient living on his customary diet. A comparison of the sugar and urea in the urine with the carbohydrates and proteids of the food for the same period shows the amount of carbohydrates unassimilated and indicates the fate of this portion of the proteid molecule. He then endeavors to gradually make the patient "sugar free," and having accomplished this result keeps the patient on the diet required for this purpose for a few days. Small quantities of carbohydrates are then allowed and the "tolerance" of the particular individual for sugars and starches estimated.

"I am moreover of the opinion that the diabetic needs bread surrogates as little as any especial form of food. It is only the preparation and combination of the food materials which demand certain precautions —except for this the diabetic can eat, so to speak, what a healthy person enjoys." It would be a pleasure to record the many helpful little wrinkles Lenné inserts, but for these we must refer the reader to the original.

All drugs have failed the author, though opium has been of service in combating special symptoms. The administration of sodium bicarbonate continuously or for alternate weeks is recommended.

[1] A most interesting summary of statistics bearing on this point can be found in Williamson's Diabetes Mellitus and its Treatment. Macmillan, 1898.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 17, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ACCIDENTS AND LAWSUITS.

THE recent trolley-car accident in Connecticut, the frequent mishaps on the electric roads in Brooklyn, N. Y., and the shocking loss of life through a defective wharf at Bar Harbor, bring once more before our minds the ever-present problem of the relations of corporations and companies to the people they are supposed to serve. From time to time our sympathies and feelings waver between the claims of those injured and the attitude of defence at all hazards of the corporations held responsible. It requires but a small measure of observation to see that the travelling public has, in general, brought itself to a frame of mind in which it is ready to grasp at merest trifles if thereby it may gain some money reward. There can be no doubt that this, in itself, is pernicious and provocative of considerable injustice both to the individual involved as regards his personal health, and also to the company as regards its money liability. That verdicts in such cases are often unjust and exorbitant is notorious, and that juries are apt to be prejudiced in favor of the individual is a no less commonplace observation.

To one of a judicial frame of mind the existing state of affairs seems not infrequently a travesty on justice, so trivial frequently are the original grounds for which suit is brought, which must at the end often, of a long period of waiting, to the plaintiff's physical detriment, be so dearly paid for by the corporation concerned.

This is one standpoint. When we contemplate the accidents of the past few weeks, all due ultimately to human carelessness, our attitude changes. The feeling is forced upon us with growing conviction that any and all means which will force upon those responsible for large numbers of lives the necessity of every conceivable precaution against accident must be taken, and if they are not, that the companies must be held responsible to the utmost limit for the injuries and death resulting. There is absolutely no question that the immanence of lawsuits has such a deterrent effect; that it inculcates precaution, and thereby increases the safety of the people at large. We know of no other means which could bring this about in like measure, and in the light of a great accident and the enormous suffering of which it is the source, we should certainly in every possible way bring those responsible to a realizing sense of the full extent of their responsibility.

We are optimistic enough to think that the present arrangement is, on the whole, conducive to the best results. If the people at large can be restrained from pressing false and insufficient claims, and if the responsible corporations can be held in wholesome restraint and continual watchfulness, through fear of the law, there will be attained, no doubt, the maximum of justice. To accomplish this we need an improved public sentiment among the claimants for damages, and an ever increasing vigilance on the part of the courts in discovering liability.

We recall on one occasion hearing a sociologist of prominence say that the questions of the relations between corporations and the people at large are assuming a vast social significance, quite apart from their medical or legal bearing. As civilization advances this must, no doubt, be more and more the case. In the meantime, it is desirable to bring about as far as may be, a just relationship between the two, by education on the one hand, and rigid legal control on the other.

A NEW HOSPITAL BUILDING FOR DEER ISLAND.

AN addition is soon to be made to the existing hospital of the Penal Institution's Department at Deer Island. As our readers no doubt know, there has for many years been in operation at Deer Island an excellently equipped hospital for the treatment of persons either sick at entrance to the institution or of those contracting disease during their stay. Naturally the demands for treatment are not great at any time, nevertheless in so large a population as the island unfortunately has, there is rarely a time when the existing wards are not more or less full.

There has up to this time been no adequate means of isolating patients suffering from venereal disease and tuberculosis from other inmates, to whom they might be a menace, nor of properly secluding patients sent to Deer Island temporarily, pending an expert opinion as to their sanity.

The projected addition to the present hospital buildings is designed to accomplish this end. It will be connected with the existing hospital by a corridor; 160 feet in length, and so protected that communication between the two divisions may be absolutely controlled. The main part will consist of a central rotunda, 35 feet square, from which will radiate four wings, 25 feet wide and 68 feet long. Each wing will have ten beds in the open wards, a diet kitchen, a linen room, a toilet apartment and an isolation ward.

The wards will be single stories, with a pitch roof, the rotunda one and one-half stories high. All the rooms will have a clear story, and be heated by indirect radiation, the corridors to have the direct heating. The wards for consumptives will be at the left, each of which will have a sun-room at the extreme ends.

There will also be an observation ward somewhat separated from those just described, which will be provided with three separate rooms. This arrangement will no doubt facilitate the speedy determination of mental defects in those sent for that purpose, and add greatly to the convenience of the hospital.

The addition of such a building is a distinct step in advance. Isolation of certain cases at public institutions is at present a decided need; the fact that this step has been taken at Deer Island reflects much credit on the policy of the existing administration.

THE DANGERS OF OVER-ENTHUSIASM.

A hobby, even if it be a so-called scientific hobby, is a dangerous thing. There is a strong tendency in the human mind, which facts often do little to controvert, to see what it wishes to see, and what most conduces to the particular end it may have in view. Examples of this are not far to seek; we see it in the enthusiasm which finds a specific virtue in a certain drug that others find inefficacious, or in devotion to a theory which only half explains, or again, in literary lines, we cannot but suspect that whatever the ultimate truth may be, the adherents of the Baconian hypothesis would see more correctly could their ardor for their theory be somewhat cooled.

On the other hand, it is through such enthusiasms that results are gained, and there are after all always enough who think differently to keep the balance fairly even. Enthusiasm which ceases to be reasonable quickly meets with as vigorous an opposition. In the field of criminal anthropology and the determination of conditions of degeneracy, the spirit of over-enthusiastic research has run riot within the last few years. Statistics here are peculiarly fallacious, inasmuch as the whole physical and mental structure of the person must be taken into account, a fact which has been too often overlooked by investigators. The so-called degenerate ear is a case in point. We would suggest to our readers that they study all ears in an electric car for example, or in their own circle of acquaintances, and then compare them with the ears of a recognized degenerate type, as of criminals or paupers. It will quickly be apparent how meaningless this sign in itself is. We were interested a few weeks since in noting what excellent and undegenerate ears the residents of a school for feeble-minded had, quite up to the average of what one sees everywhere. And yet we still find noted in medical papers details of ears as signs in themselves of degeneracy.

The work of Prof. Cesare Lombroso has long seemed to us an example of the danger of over-enthusiasm. To the frame of mind into which he has worked himself by much excellent observation, all facts which to others are indifferent, or indications, perhaps, of special fitness, are proof of the essential correctness of his standpoint. The following clipping from the *British Medical Journal* shows the type of reasoning to which we refer:

"Prof. Cesare Lombroso, who has had an opportunity of studying casts of the cerebral convolutions and microscopic preparations of the brain of Vacher, *l'eventreur*, guillotined at the end of last year, has satisfied himself that the French 'Jack the Ripper' presented all the characters of the epileptic and congenital criminal. In both hemispheres, but particularly in the left, there was a communication between the Rolandic and Sylvian fissures; on the right side the latter also communicated with the post-Rolandic fissure. On the left side, the foot of the ascending parietal convolution presented several abnormal sulci; the fissure of Rolando ended above in a bifurcation on both sides; on the left side the interparietal fissure did not communicate with the post-Rolandic fissure, and was broken by numerous folds. Histological examination by Nissl's method of a small portion of the frontal lobe revealed atrophy of both granular layers, enlargement of the pyramidal cells, which were also very scanty in number, and the existence of a certain number of nerve cells in the white matter."

To a man armed with a preconceived theory, the cerebral convolutions have always been a tempting field, but we had supposed that investigation had long since gone beyond the point of attributing significance to anomalies of the Rolandic or other fissures and gyri, or to the examination of a "small portion" of the frontal lobe. Such superficiality strikes us as beyond measure unscientific. The foregoing may, no doubt, be incorrectly reported, but it serves to illustrate our point that enthusiasm has its dangers, and that its results are always to be taken with a conservatism proportionate to the degree of the enthusiasm.

MEDICAL NOTES.

Professor Röntgen called to Munich. — Prof. C. W. Röntgen, of Würzburg, has received a call to the University of Munich.

Small-Pox Outbreaks. — Up to August 3d there had been, according to the *Medical News*, some thirty cases of small-pox in Pittsburg and neighboring towns, all of which places are on the line of the Pennsylvania Railroad. No money has been appropriated for the establishment of a quarantine, and an appeal has been made to the Westinghouse Electric Company for funds for the purchase of vaccine virus and for quarantine expenses. An epidemic of small-pox has broken out in Claiborne County, Tenn., on the Kentucky border. It is believed that the efforts

of the authorities to prevent the spread of the disease will be successful.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, August 16, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 59, scarlet fever 10, measles 7, typhoid fever 18, small pox 1.

Vaccination at Everett. — No new cases of small-pox have developed at Everett, and the Board of Health has discontinued free vaccination. The infected district will, however, be quarantined for several days.

Typhoid Fever at Jamaica Plain. — The small epidemic recently reported at Jamaica Plain has subsided. No new case has been reported from the infected district for more than a week.

Quarantine against Virginia Ports. — The quarantine against vessels from Virginia ports on account of yellow fever was recently raised. Since August 2d, when the quarantine was ordered, eleven vessels have arrived from Chesapeake Bay. None of them were infected.

Cholera Infantum. — There has been a less number of cases of cholera infantum during the past week than for the corresponding week last year, the figures being twenty-seven this year, sixty-seven last year. This is no doubt due to the unusual weather conditions.

Poor Schoolhouse Plumbing. — Owing to the unusual frequency of contagious diseases in Cambridge this spring, attention has been directed to the sanitary conditions of the schools. A thorough investigation is now under way, with the result that much of the plumbing has been found to be in an extremely defective state. It is stated, for example, that in the new English High School, which was completed about eight years ago and is a very expensive building, over two hundred leaks were found in the piping.

NEW YORK.

Small-Pox at Niagara Falls. — There have been a number of cases of small-pox recently at Niagara Falls, and on August 9th three additional cases were reported. The State Board of Health has succeeded in tracing the origin of the outbreak to a patient in whose case a mistaken diagnosis of chickenpox was made.

A New Veterinary College. — It is announced that the two veterinary colleges, the New York College of Veterinary Surgeons and the American Veterinary College, have been consolidated, and will hereafter constitute the veterinary department of the University of the City of New York. The school is to be known as the New York American Veterinary College, and it will be on a like footing with the six other schools of the University. The College of Veterinary Surgeons was chartered in 1857, and the American Veterinary College in 1875, and Prof. Alexander F. Liantard of the latter institution is to be the Dean of the Faculty of the consolidated school. Most of the Faculty have been taken from the two colleges, Dr. Liantard being professor of anatomy, clinical surgery and veterinary jurisprudence, but some of its members are new appointments. Among the latter are Dr. Edw. K. Dunham, of the University and Bellevue Hospital Medical College, professor of comparative pathology; Dr. William H. Park, of the same school, professor of bacteriology; and Dr. J. B. Stein, of the New York Dental College, professor of physiology. In a statement in regard to the consolidated school issued by Chancellor McCracken of the University, he says: "These two schools have outranked in age all other veterinary schools in the country, and have educated more than one thousand veterinary surgeons. Like the veterinary school of Harvard University and that of the University of Pennsylvania, this school is placed upon a strictly university footing. Co-ordination and co-operation with the University and Bellevue Hospital Medical College will thus be secured to the advantage of both schools and of medical science, and to the promotion of the health of the community. In order to enter the school a student must have obtained forty-eight counts in a Regent's examination, this being considered the equivalent of a high-school education. The Regents have been gradually raising the requirements for admission to the professional schools, and in this I think they have performed an important public service."

Arrest of Four Attendants at Manhattan State Hospital. — Four keepers of the Manhattan State Hospital for the Insane on Ward's Island have been arrested on the charge of killing a paretic patient in the institution on August 5th. The case was reported to the Board of Coroners by Dr. Percy Bryant, the Medical Superintendent, who stated that the patient, who was thirty-four years of age, had been a powerful man and a wrestler. On the morning of the 5th he struck one of the attendants in the neck with his fist. He was then held on the floor by three attendants, who had come to the assistance of the first, until his paroxysm subsided. He then washed his face, returned to the ward, sat down in a chair, and became very pale. A physician was immediately sent for, but the patient died in a few minutes. The official report of coroner's physician, Dr. Hamilton Williams, of the autopsy made by him declared that death resulted from hemorrhage and shock. Among the injuries noted were fracture of six ribs and bruising of the intestines, with a rupture of the peritoneum.

Fire at Fort Hamilton Hospital. — A fire which caused considerable excitement, but which was extinguished before more than a few hundred dollars' damage was done, occurred early in the morning of August 7th in the military hospital at Fort Hamilton.

There were fourteen patients in the wards at the time, but all were promptly removed as soon as the fire was discovered.

Gift of an Ambulance. — A lady of Sing Sing who desires that her name shall be withheld has presented, through Dr. W. A. Winer, a handsomely appointed ambulance, costing about $600, to the Ossining Hospital in that place.

Death rather than a Bath. — The warden of the Hudson County Jail at Jersey City is authority for the statement that Giacomo Moreda, an Italian wife murderer, who committed suicide on August 8th, killed himself to avoid taking a compulsory bath. The man had not washed his face or hands during the three months he spent in jail, and death appears to have been preferable to him to being placed in a tub and scrubbed till he was clean, a treatment that was ordered for him in order that he might be in a fit condition to put on a new suit of prison clothes which the warden had provided.

Death from Starvation. — The Rev. J. Hughes Parry, fifty-four years of age, a native of Wales and pastor of the Moriah Welsh Calvinist Methodist Church of Utica, N. Y., died on August 8th of exhaustion following a fast of forty-eight days, undertaken in the hope of curing himself of chronic intestinal catarrh, a disease of which his father is said to have died. After the first two weeks he had no desire for food, but he lost thirty-six pounds and his strength gradually failed.

Death of I. C. Schureman, M.D. — Dr. I. C. Schureman, who had practised in Toms River, N. J., for thirty years, died at his home in that place on August 6th. He was fifty-nine years of age, and was an army surgeon in the latter part of the Civil War.

ARMY NOTES.

The Mortality in the Army. — The records of the Adjutant-General's Office show that between May, 1898, and June 30, 1899, the mortality in the army from all causes was 6,605, of whom 5,907 died of disease. The deaths from disease in the United States were 4,091. In Manila and the Philippines, where active field operations have been carried on almost constantly, the mortality from disease, with an average strength of about 24,000, was 380.

Strength of the Medical Corps in the Philippines. — The present strength of the medical and hospital corps *personnel* now in the Philippines or under orders to proceed thereto includes 227 medical officers, 1,175 members of the hospital corps and 27 female nurses. The number of the latter is to be increased at an early date, there being altogether about 200 in the service. To this strength must be added a varying number of Chinese coolies, who do nearly all the work as litter bearers as well as the heavier labor about the hospitals.

Miscellany.

SUMMER MORTALITY IN NEW YORK.

The summer mortality in the city this season compares favorably with that in past years. The deaths reported in four weeks in July represented an annual death-rate of 22.73+, against 17.98+ for four weeks in June, and 17.55+ for four weeks in May. The maximum death-rate, 24.28, was reached during the week ending July 15th, and this period of highest mortality is exactly in accordance with the average figures for many years. The lowest death-rate reported for many months was in the week ending June 17th, namely, 15.73. Excluding the week ending on the 10th, when the rate ran up to 21.49, the average death-rate for June was only 16.81. The mortality from sunstroke has been unusually low this year. Excluding the weeks ending June 10th and 17th, when the deaths from this cause numbered 85 and 30 respectively, the weekly average since the first of June has been 2.66, and in several weeks there has been but a single death from sunstroke. Notwithstanding the intense heat of the earlier portion of June, the mortality from diarrheal diseases was very much greater in July than in that month. For four weeks in June the weekly average of deaths was 67.5, and in children under five years of age, 64.25; while for four weeks of July the weekly average was 316.75, and in children under five, 294.25.

Deaths from small-pox have of late years been very rare in New York, but during the week ending May 27th three were reported, and in the month of June there were nine fatal cases. In July, however, there was but a single death. The weekly average of deaths from diphtheria in July was 35, against 36 in June, and 27.5 in May; from scarlet fever, 7.75, against 15 in June and 13.5 in May; from measles, 11.25, against 19.25 in June, and 16.5 in May. Rather curiously, the mortality from pulmonary tuberculosis was somewhat greater in July than in June, the weekly average of deaths being 149, against 134.5 in June, and 158.75 in May. In pneumonia, however, there has been a progressive decrease in the number of deaths as the summer advanced, the weekly average being 171 in May, 128.25 in June, and 102.5 in July.

THE INTERNATIONAL CONFERENCE FOR PROPHYLAXIS OF SYPHILIS AND VENEREAL DISEASES.

We have received from Dr. Isadore Dyer, of New Orleans, who has been delegated by this Conference to investigate the conditions of prostitution in the United States, a letter calling attention to this important meeting, to be held in Brussels, September 4th and following days. Papers are to be read by Drs. Fournier, of Paris; Neisser, of Breslau; Lassar, of Berlin; Finger, of Vienna; and by a number of others prominent as students of those questions. The committee has indicated the following as delegated to investigate conditions of prostitution in their respective countries:

Argentine Republic, Dr. Baldomero-Sommer, of Buenos Ayres; Austria, Dr. Finger, Vienna; Belgium, Drs. Bayet and J. Verhoogen, Brussels; Bosnia, Dr. Gluck, Savajevo; Chili, Dr. Valdes-Morel,

Santiago; Denmark, Dr. Ehlers, Copenhagen; England, Dr. Geo. Ogilvie and Dr. Drysdale, London; France, Dr. Ozenne and Dr. Julien, Paris; Germany, Drs. Blaschko, Berlin, and Neisser, Breslau; Hungary, Dr. Rona, Budapest; Holland, Dr. Selhorst, The Hague; Italy, Dr. Tommasoli, Palermo, and Dr. Bertavelli, Milau; Norway, Dr. Axel-Holst, Christiania; Roumania, Dr. Petrini de Gakatz, Bucharest; Russia, Dr. Petersen, St. Petersburg; Sweden, Dr. Welander, Stockholm; Switzerland, Drs. Jodassohn and Schmid, of Berne; Turkey, Dr. Von Duhring and Dr. Zotos, Constantinople; United States, Dr. Isadore Dyer, New Orleans.

With a view to making some presentations as to the conditions of prostitution and venereal diseases in the United States Dr. Dyer has sent out a list of questions calculated to elicit the desired information to every city in the United States of 20,000 or more inhabitants.

SMALL-POX IN GERMANY.

THE antivaccinationists will find food for thought if they will investigate the latest reports concerning small-pox in Germany during the last decade and a half. For the ten years previous to 1895 the average death-rate from small pox was 116, the greater of the total number occurring in the early period of the decade. In 1895 there were 27 deaths, in 1896, 10, and in 1897, 5. In Germany the law requires vaccination and revaccination, and the law is carried out. In no other country is the value of vaccination more evident than in Germany, and in no other country is the preventive method more thoroughly carried out. — *Journal of the American Medical Association.*

JOHN HENRY GILBERT, M.D.

RESOLUTIONS OF THE NORFOLK SOUTH DISTRICT MEDICAL SOCIETY.

THE fellows of the Norfolk South District Medical Society have received with the deepest sorrow the announcement of the death of their beloved and honored associate, Dr. John Henry Gilbert, of Quincy, who died on August 2, 1899.

In his death this Society has sustained the loss of an ardent fellow-worker, a consistent member of the medical profession and a skilful physician and surgeon.

He was a faithful attendant at the meetings of the Society, and in its deliberations exhibited a mind well informed in the most advanced thought of medical science.

He filled the office of Censor-Councillor and President with ability, zeal and faithfulness, and endeared himself to all the members by his kindly disposition, courteous manner, upright conduct in medical ethics, and friendly interest in the welfare and success of his fellow-physician.

His reputation was not confined to the city of Quincy, but throughout the State he was recognized by his professional brethren as an honored and honorable physician, who in accuracy of diagnosis, clearness of statement and judicious treatment was surpassed by none.

The memory of his pure life and devotion to the profession which he loved and honored will remain as a blessed heritage and an incentive to noble work by his associates in this Society.

The fellows of this Society tender to his bereaved family their sincere sympathy in this hour of deep affliction and loss.

Resolved, That this memorial be entered upon the records of the Society, and a copy of the same be forwarded to the family of our associate, and also to the Quincy papers and the *Boston Medical and Surgical Journal* for publication.

E. G. TINKHAM, M.D., *President*,
JOHN F. WELCH, M.D., *Secretary*.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUGUST 5, 1899.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.

Newburyport	14,915	3	2	—	—	—	—	—
Melrose	14,032	4	3	25.00	—	—	—	—

Deaths reported 2,890; under five years of age 1,280; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 696, consumption 256, acute lung diseases 144, diarrheal diseases 517, diphtheria and croup 53, typhoid fever 48, cerebro-spinal meningitis 26, whooping-cough 22, scarlet fever 12, measles 10, erysipelas 9.

From cerebro-spinal meningitis New York 11, Boston, Baltimore, Washington, Worcester and Chelsea 2 each, Cambridge, Somerville, Brockton, Quincy and Pittsfield 1 each. From whooping-cough New York 15, Philadelphia, Boston and Cambridge 2 each. From scarlet fever New York and Philadelphia 5 each, Boston 2. From measles New York 8, Providence and Melrose 1 each. From erysipelas New York 5, Philadelphia and Boston 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,406, for the week ending July 29th, the death-rate was 20.7. Deaths reported 4,629; acute diseases of the respiratory organs (London) 169, diarrhœa 807, measles 119 diphtheria 76, whooping-cough 60, fever 26, scarlet fever 23, small-pox (Hull) 2.

The death-rates ranged from 11.5 in Cardiff to 29.7 in Liverpool; Birmingham 21.1, Bradford 16.3, Bristol 13.6, Gateshead 13.7, Hull 18.7, Leeds 21.2, London 21.6, Manchester 24.1, Newcastle-on-Tyne 14.8, Nottingham 20.9, Portsmouth 19.7, Salford 25.3, Sheffield 27.6, Swansea 15.6, West Ham 25.2.

METEOROLOGICAL RECORD

For the week ending August 5th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 12, 1899.

J. R. WAGGENER, medical inspector, promoted to medical inspector from April 9, 1899.

T. H. STREETS, medical inspector, promoted to medical inspector from April 16, 1899.

T. A. BERRYHILL, surgeon, promoted to surgeon from April 9, 1899.

E. P. STONE, surgeon, promoted to surgeon from April 16, 1899.

J. M. MOORE, passed assistant surgeon, ordered to the "Vermont," August 10th.

B. L. WRIGHT, assistant surgeon, detached from the "Vermont" and ordered to duty with the 2d Marine Battalion for Manila, P. I., and on arrival at Manila to report to the commander-in-chief of the Asiatic Station for duty.

W. F. ARNOLD, passed assistant surgeon, granted extension of sick leave for a month.

G. PICKRELL, passed assistant surgeon, authorized to drop middle initial of name. Detached from the "Baltimore" and ordered to the "Monterey" and to the Cavite Naval Station.

H. H. HAAS, assistant surgeon, detached from the "Oregon" and ordered to the Naval Hospital, Yokohama, Japan, for treatment.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FOURTEEN DAYS ENDING AUGUST 10, 1899.

WASDIN, EUGENE, surgeon. To proceed to National Soldiers' Home, Va., for special temporary duty. July 29, 1899.

MAGRUDER, G. M., passed assistant surgeon. To proceed to Hampton, Va., for special temporary duty, reporting at the Bureau en route. July 31, 1899. So much of Bureau order of July 31, 1899, directing Passed Assistant Surgeon Magruder to proceed to Hampton, Va., revoked, and directed to proceed to Richmond and Newport News, Va., for special temporary duty. August 3, 1899.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Hampton, Va., and report to Surgeon J. H. WHITE for special temporary duty. July 30, 1899.

SMITH, A. C., passed assistant surgeon. Leave of absence granted by Bureau letter of June 20, 1899, revoked and directed to rejoin station at Norfolk, Va. July 31, 1899.

STIMPSON, W. G., passed assistant surgeon. To proceed to Fort Monroe, Va., for special temporary duty, reporting at Bureau en route. August 1, 1899. So much of Bureau order of July 31, 1899, directing Passed Assistant Surgeon Stimpson to proceed to Fort Monroe, Va., revoked, and directed to proceed to Newport News, Va., and report by wire to Surgeon J. H. WHITE, Hampton, Va., for orders. August 3, 1899.

BLUE, RUPERT, passed assistant surgeon. To proceed to Columbus City, Washington, for special temporary duty. August 3, 1899.

SPRAGUE, E. K., passed assistant surgeon. Leave of absence granted by Bureau letter of July 27, 1899, revoked. July 31, 1899.

WICKES, W. H., passed assistant surgeon. Leave of absence granted by Bureau letter of July 27, 1899, revoked. July 31, 1899.

VON EZDORF, R. H., assistant surgeon. To report to Surgeon J. H. WHITE, at Hampton, Va., for special temporary duty. July 31, 1899.

FRICKS, L. D., assistant surgeon. Relieved from duty at the South Atlantic Quarantine Station and directed to proceed to Hampton, Va., and report by wire for further orders. August 1, 1899.

THORNBURY, F. J., assistant surgeon. To proceed to Cleveland, Ohio, for temporary duty. July 28, 1899. Bureau order of July 28, 1899, directing Assistant Surgeon Thornbury to proceed to Cleveland, Ohio, for temporary duty revoked. July 31, 1899. Relieved from duty at New York, N. Y., and directed to proceed to Baltimore, Md., and report to the commanding officer for duty and assignment to quarters. August 1, 1899.

BEAN, L. C., acting assistant surgeon. Granted leave of absence for fourteen days from August 4, 1899. August 3, 1899.

GIBSON, L. P., acting assistant surgeon. Granted leave of absence for ten days. July 29, 1899.

MCGINNIS, R. H., acting assistant surgeon. Granted leave of absence for three weeks from August 7, 1899. July 28, 1899.

MARTIN, H. McD., acting assistant surgeon. Granted leave of absence for thirty days on account of sickness. August 2, 1899.

SMITH, A. W., acting assistant surgeon. To proceed to Fortress Monroe, Va., and report to Surgeon W. J. PETTUS, for special temporary duty. August 1, 1899.

RODMAN, JOHN C., sanitary inspector. Granted leave of absence for four days. August 1, 1899.

KOLB, W. W., hospital steward. To proceed to Hampton, Va., and report to Surgeon J. H. WHITE for special temporary duty. August 1, 1899.

PECK, F. H., hospital steward. To proceed to Fortress Monroe, Va., and report to Surgeon W. J. PETTUS for special temporary duty. August 2, 1899.

DAVIS, H. E., hospital steward. To proceed to Baltimore, Md., and report to commanding officer for temporary duty. August 2, 1899.

OLSEN, E. T., temporary hospital steward. Relieved from duty at Chicago, Ill., and directed to proceed to Wilmington, N. C., and report to commanding officer for duty and assignment to quarters. August 2, 1899.

BROOKS, S. D., surgeon. To proceed to Augusta, Maine, for special temporary duty. August 5, 1899.

BLUE, RUPERT, passed assistant surgeon. To proceed to Columbia, Washington, for special temporary duty. August 6, 1899.

FRICKS, L. D., assistant surgeon. To report to Passed Assistant Surgeon A. C. SMITH for duty. August 5, 1899.

TODT, W. C., acting assistant surgeon. Granted leave of absence for seven days. August 6, 1899.

RICHARDSON, S. W., hospital steward. To report at Washington, D. C., for assignment to special temporary duty. August 5, 1899. To proceed to Norfolk, Virginia, and report to Passed Assistant Surgeon A. C. SMITH for temporary duty. August 7, 1899.

GIBSON, FRANK L., hospital steward. Relieved from duty at the Delaware Breakwater Quarantine Station and directed to report at Washington, D. C., for temporary duty. August 9, 1899.

COMFORT, N. C., hospital steward. To proceed to Hampton, Virginia, and report to Surgeon J. H. WHITE for temporary duty. August 8, 1899.

RESIGNATION.

DE KRAFFT, S. C., acting assistant surgeon. Resignation accepted to take effect July 15, 1899. July 26, 1899.

APPOINTMENTS.

B. W. GOLDSBOROUGH, of Maryland, appointed acting assistant surgeon, U. S. Marine-Hospital Service, for duty at Cambridge, Md.

EGIL T. OLSEN, temporary junior hospital steward, appointed junior hospital steward from May 29, 1899. August 3, 1899.

CHARLES A. WARHANIK, of Illinois, to be junior hospital steward. August 5, 1899.

PROMOTIONS.

G. M. MAGRUDER, passed assistant surgeon, commissioned as surgeon. August 5, 1899.

J. J. KINYOUN, passed assistant surgeon, commissioned as surgeon. August 5, 1899.

RECENT DEATH.

LAWRENCE GRAFTON KEMBLE, M.D., M.M.S.S., of Salem, died August 7, 1899, aged thirty-seven years.

Address.

ADDRESS IN SURGERY.[1]

BY ALEXANDER OGSTON, M.D.,
Surgeon-in-Ordinary to Her Majesty the Queen in Scotland; Regius Professor of Surgery, University of Aberdeen.

(Concluded from No. 7, p. 151.)

In all that pertains to surgical work, it will not be questioned by those aware of what is now required, that our military and naval surgeons have, in peace, virtually no training to fit them for what they may at any instant be called upon to undertake in war. Who that compares the conditions under which the civil surgeon is formed with those existing in the Royal Army Medical Corps or the navy will be so bold as to say that the latter furnish any adequate means of familiarizing their surgeons with the highly complicated and difficult procedures which they ought to be able to carry out with dexterity and success? Save a few connected with Netley — and perhaps Haslar — Hospitals, most officers have hardly once in their lives an opportunity of carrying out an important operation on the brain, thorax, or abdomen. How, then, can they undertake, with any prospect of a happy issue, the intricate steps of, say, a laparotomy in a gunshot wound of the abdominal contents, with all its complicated problems and perils? Under the existing system no junior officer of the Royal Army Medical Corps has any opportunity of practising modern surgery; even if an occasion offers, he is tied down by restrictions and impediments enforced by his seniors, and his natural desire to prepare himself for the highest work is disregarded and repressed, so that few, if any, are capable of the class of surgical work which will be expected of them by the country, and for the non-performance of which they will be unjustly blamed when the test of war is imposed upon their performances. So long as the medical services afford their surgeons no proper facilities for acquiring and maintaining a competent knowledge of these highly-important and necessary matters; so long as the junior medical officers have neither the chance nor the encouragement to perfect themselves in their science, and especially in what would lie before them in the event of a war, it can hardly be wondered at that a service entailing on those who enter it what is, from a professional point of view, almost an intellectual sterility, should be a mode of life our best graduates recoil from, and which few of them can be persuaded to adopt.

THE WANT OF ADEQUATE TRAINING.

Moreover, the destitution of the army and navy of institutions where surgery can be practised is very great. Netley Hospital, limited as it is to the treatment of soldiers, and Haslar to that of sailors, do not offer such varied material as is required by surgeons and physicians to cultivate the practical branches of their art. And there is an almost total absence of hospitals and lazarettos throughout the stations where medical officers are serving of a kind fitted to afford them any of the facilities they have a right to expect. The provision of places of study and practice is imperatively called for, where the younger and middle-aged officers, provided with all the appliances found in civil institutions, and with every class of patients on whom they may be used, may fit themselves for their duties of attending the wounded during action or in field or base hospitals. And until such provision is made, we may be assured the services will not secure the number and quality of officers they require; for graduates will not nowadays, after being fashioned by years of high mental training, consent to exchange an intellectual profession for a life of stagnation. The services must either adapt themselves to the altered spirit of the times, or remain undermanned and officered by a class of graduates inferior to those who would otherwise enter them.

Had custom not dimmed our eyes, the position of matters in the army and navy would ere now have excited indignant surprise. While the calls of modern science have been heard in the surgery and medicine of civil life, and effected the changes to which I have alluded, and while they have been taken to heart in the medical services of foreign armies and navies, they have fallen on unheeding ears among those responsible for the efficiency of our own. The contrast between the medical and other departments makes the matter more astonishing. Such scientific corps as, for instance, artillery, engineering, and telegraphy have undergone extensive improvements and reforms in the last few decades. No means of enhancing their efficiency is neglected. For them all the inventions of modern science are studied, adopted, and improved. Elaborate care is taken that every one whose duties in war time will necessitate his familiarity with appliances or knowledge of any kind is trained in them, so that when the call of war is heard, perfect efficiency shall have been attained. The lives of the officers and men of the navy, of the royal engineers and artillery, of the cavalry and infantry, are devoted to the daily acquirement of a knowledge of and familiarity with what they must use in war, attainable only by constant practice under conditions resembling as nearly as may be those of a real campaign. Tactics are studied, manœuvres held, officers and men practised and drilled, fleets and bodies of men are put in motion, and any unreadiness is observed and remedied. Yet the Royal Army Medical Corps and the Naval Medical Service, which demands an even higher and more varied culture, a more profound knowledge, and a greater degree of practice and experience than either artillery or engineering ere their delicate machinery can be brought into salutary use, are left in a condition which may have answered well enough fifty years ago, when rough-and-ready surgeons could do the rough-and-ready work then required, but which is out of harmony with the revolutionized conditions of modern surgery and the state of the medical service of the armies and navies of rival military powers. Even the care that has been bestowed on the development of ambulance will only result in wounded men being now brought, on the best surgical principles, to surgeons rendered as unfit to treat them as it is possible for a bad system to make them.

CAUSES OF DISCONTENT IN THE SERVICES.

The present system has had a sufficient trial, and, in spite of all attempts to amend it, has yielded unsatisfactory results, mainly owing to the deficiencies indicated. The Royal Army Medical Corps and Navy

[1] Read at the annual meeting of the British Medical Association at Portsmouth, August, 1899. - Abstract from advanced proof-sheets sent by the courtesy of the editor of the British Medical Journal.

Medical Department, indeed, are at present existing under impossible conditions; they cannot be subjected to such impediments without their effects being felt in a hundred ways. They are in a state of internal discontent from the consciousness of being seriously defective somewhere. Their members realize that they do not possess the same privileges of professional occupation as their civil *confrères*, and are sensible that they are not equipped as they ought to be in following out the intellectual problems to which they have dedicated their lives. This is perceived not only by themselves but by others, especially by the other scientific branches, and naturally they do not enjoy the same appreciative esteem as is accorded to departments engaged in the constant healthful exercise of all their due activity, and possessing the internal vitality and self-respect resulting from conscious advance in the exhilarating race of intellectual progress which forms the very life of the leading professions in the world's foremost nations. It is certain, too, that the same cause underlies what has often been complained of, namely, the cold regard paid by the military and naval authorities to the medical services, their lack of appreciation of them, the way in which they are starved in their pecuniary requirements, and the fashion in which their exercise and training during peace are overlooked and neglected. They would seem to be considered as less deserving of development than even such departments as the commissariat and transport — the contemptuous belief being apparently held that trained surgeons to attend the wounded in war can be summoned into the field at a moment's notice by the expenditure of so much money, like the horses, mules and camels that an army requires.

THE ARMY MEDICAL SERVICE UNDERMANNED.

This condition of things is one from which there must some day be a rude awakening. It may be true that in former days an army medical service could be so extemporized, but it is so no longer. The Army Medical Corps ought to be made, what it at present is not, a complete and perfect entity, fully equipped with everything needful, and regularly trained like any other department. If it is to furnish the priceless service for which it exists, it must be fully manned, the members composing each of its units must be accustomed to work together, so that their duties are familiar and can be promptly performed, and the whole of its equipment must be prepared in time of peace for instant employment in war. Instead of this we have a department so starved and undermanned that, as the Under Secretary for War recently admitted, in the event of a war breaking out requiring the employment of two army corps, we could not supply them with the requisite medical contingent.

So complex an organization as the Royal Army Medical Corps ought to be kept in a high state of efficiency, and be vitalized by continual practice. It ought to consist of separate units, each complete in itself and familiar with its equipment and work. Each field hospital should be completely furnished and frequently practised in its duties. Every corps should be ready to act, as in other departments, the moment it takes the field, and not have to learn its duties there when the day of trial comes in a campaign. Whether stationed at home or abroad, the officers should be provided with all the proper means of keeping themselves informed regarding the advances that are for ever being introduced into their science. The literature bearing on every new progress should be supplied to them at remote stations where scientific periodicals and books are not found; for no medical officer can, from his pay, purchase and transport a library of the newest medical works, even if he were aware, which he often cannot be, of what he ought to procure. The want of all these things prevents the due development of the services, and there can be no reasonable hope of a better state of matters until they are remedied. But were the reforms that naturally suggest themselves carried out, who can hesitate to believe that new life would be infused into them? The best graduates would once more flock to and remain in them; and the country would not be placed in the dreadful position of having to pay with the lives of its bravest and best for the state into which its medical services have been allowed to drift.

THE INDIAN MEDICAL SERVICE.

It is not necessary to enter into many details concerning the Indian Medical Service. To some extent it shares in the defects of the Queen's; but opportunities of professional work are more frequent, two-thirds of its officers being engaged in civil work; and it therefore affords a professional training that places it in a much better position, and approximates it in some degree to the condition of Continental army medical services. Its comparative popularity is a strong corroboration of the remarks I have just made, for it attracts the best graduates of our medical schools, so that the weakest men who enter its ranks are of a class superior to the best who enter the Royal Army Medical Corps.

THE MEDICAL DEPARTMENT OF THE NAVY.

The medical department of the navy, on which I have already partly touched, has no more than the army kept pace with the advance of the times; it still preserves an organization that may have answered its purpose well enough in the first half of the present century, but is inadequate to meet the requirements of to-day.

In it, as in the army, the fundamental error is perpetuated of adhering to a system whereby its officers, shut out from practising their profession as civil surgeons have to do, fall year by year more out of touch with the advancing requirements of science, and necessarily fail to familiarize themselves with what will be their great duties in the event of a naval war. Treating none but the healthy and strong in time of peace, their opportunities of dealing with wounds, and especially with the higher branches of surgery, are as good as non-existent; and they cannot by any possibility, as things are, acquire the skill everywhere possessed by surgeons engaged in civil work, but which would in war be equally demanded of them. Such as it is, their work has to be carried out under arrangements that seem deliberately calculated to render the practice of antiseptic or aseptic surgery impossible in rooms without antiseptic materials, irrigators, or sterilizers, and with a limited armamentarium of instruments provided, even at the present time, at their own expense. Proper diagnostic instruments and apparatus do not exist among them; even the surgeons in the best equipped vessels and stations are left destitute of the facilities that are wanting in

hardly a single civil hospital or dispensary for the poor throughout the length and breadth of the land.

Nearly all that has already been stated regarding the Royal Army Medical Corps is at least equally true of the Naval Medical Service; but to enter *seriatim* into these matters again would be an unjustifiable waste of time. More than the army the navy requires the touch of a reformer's hand. I should be sorry to use any word that may give needless offence, but I am forced to say that even on board the most modern ships of war a comparison of their surgical outfit and arrangements with the varied armamentarium and the conditions of work of the civil surgeon tends to evoke a vision of the knight of La Mancha equipped in his great-great-grandfather's suit of armor.

When we consider what the medical officers of the navy may at any moment be called upon to do, and their vast importance to the country, we feel that they, of all others, ought to be almost lavishly supplied with the best facilities for work, with instruments and apparatus of all kinds, instruments for special diagnosis, instruments for special operative procedures, endoscopes, electrical instruments, radioscopic apparatus, sterilizers, and apartments where antiseptic and aseptic surgery can be practised, and have reasonable opportunity in time of peace of familiarizing themselves with their use. The highest care should be bestowed on fostering the British of all the naval medical services in the world, and we can scarcely believe that this is not done.

THE WOUNDED IN NAVAL WARFARE.

In the event of a naval engagement of any magnitude the wounded on board our ships of war would have to be attended to in a small dark room, unprovided with any save the rudest appliances and a few cots, where at most half a dozen men could be handled, and which is moreover in many vessels as much exposed as any other part of the ship to the fire of the enemy. Were such a fighting-bay rendered untenable, the wounded, however great their need, could be attended to only by being lowered, slung in a vertical posture, down the narrow hatchways, where the shot is brought up from the magazines to the guns, and even these would not be available during the heat of an action. Everything on board ship that can destroy life is in the highest perfection, everything that can save it is of the rudest description and behind the age. In the case of a gunshot wound through the abdomen the only chance of recovery is laparotomy performed within twelve hours, but on board none of Her Majesty's fleet is there any possibility of performing such an operation; there are neither accommodation, instruments, nor accessories. Or were 20 per cent. of the men of one of her battleships or cruisers killed and disabled in action, the wounded among them could not, in the present state of things, receive the attention that ought to be given them.

Yet there is no reason why the constructors of the navy should not arrange under the water line, shielded from the enemy's fire by the turtle-back armor-deck of the vessel, a sufficiently large and well-lit space, fitted with all that is required for wounds, compound fractures, and operations on the main cavities of the body. Into these the wounded could be lowered through hatchways made capable of transmitting men on stretchers or litters even in the midst of an engagement, so that all emergency operations could be satisfactorily performed.

Matters are even worse on board the smaller vessels, which have no surgeon and few surgical appliances. On torpedo-boat destroyers there are no materials for making splints, only a box of antiquated remedies like those supplied in the vessels of the mercantile marine, where the sailing-master acts as the doctor. It would not sensibly retard the speed of such a boat to carry a surgeon,— or at least several men specially and fully instructed in first aid, and really capable of efficiently affording it,— and to furnish such appliances as would enable them to deal with wounds and compound fractures.

The requirements of naval warfare must always, more or less, impede the carrying on of surgical work on shipboard during naval actions. No person will impugn the principle that the efficiency of war vessels as fighting machines has first to be considered, and as much accommodation as possible allotted to their fighting armanent. It is inevitable that this should be the chief consideration in fitting out the navy. To keep the communicating doors of water-tight sections open during action, in order to convey the wounded to the surgeons, might cost the lives of all on board. It may also be that in naval warfare, especially in some vessels, success may occasionally best be purchased by throwing aside for the time being all considerations of dealing with the wounded. But the principle may be, and is being, carried too far; for it is a duty to see that, short of interfering with the perfection of the fighting machine, no suffering is left unrelieved or life needlessly sacrificed, and no means neglected of bringing wounded men the earliest and best attention that can be given. No questions of economy should be allowed to prevent officers and sailors wounded in naval warfare receiving such early and effectual help as their condition so urgently demands. The cost of a couple of twelve-pounder guns would probably cover all that is required for each ship. We must lead rather than follow in all naval matters, as foreign ships of war are constructed according to the example England sets. And our navy, being the most perfect and greatest destroying force of all the war-fleets of the world, we should be the foremost in introducing into it the best-planned methods of relieving suffering and saving life that can be devised.

LINES OF REMEDY.

Criticisms without suggestions are usually better unmade, and to call attention to defects in the services without indicating the lines of remedy would be almost unpatriotic. I have already ventured to some extent to indicate how I think defects may be made good, though some of the suggestions have been more of detail than principle. It would be out of place to dwell at length upon minor suggestions, but it may now be desirable to state generally the lines on which the services can be brought into harmony with the requirements of modern science, so as to insure the wounded in war the most enlightened treatment, and for the medical officers the means and training for carrying on their work in a manner that will bear comparison with that of their civil compeers.

It would be easier to do if we possessed universal military service, as we might then look for guidance from Continental examples. In countries where this

obtains, the most eminent civil surgeons are at the disposal of the authorities in time of war, and in peace hold rank in the army, receiving promotion like those actively serving. They are soldiers in reserve, and can be made use of wherever their eminence and special qualifications make them most useful in war. The idea of adopting this system among ourselves, but on voluntary lines, is no new one; although it has recently been brought prominently into notice by Lord Lansdowne's creation of the Central British Red Cross Committee. If the committee make an endeavor to attach a number of our most capable civil surgeons to the Royal Army Medical Corps, by conferring on them military rank and titles, with special privileges and emoluments, on condition that their services be at the disposal of Government in time of war, some good may be done. There are obvious difficulties, but they do not seem altogether insuperable, and, at any rate, such a plan is worthy of the attention of the War Office. But anything short of this, as, for instance, the old desultory method of inviting civil practitioners to volunteer their aid when war breaks out, and so supply the defects of the service, is doomed to failure; because, though capable young graduates are thus obtainable in considerable numbers, they are not the class of experienced surgeons who are wanted; they cannot replace the military or naval medical officers, and are at best but a species of superior dressers. Few, if any, of the men who would be of real value will come forward, save perhaps in the event of an impending national calamity. The system was tried in the Crimea, and has since occasionally been carried out by the National Aid Society, but I am sure those who have seen it in operation must admit that it is at least a comparative failure.

Neither of these methods, nor indeed any other, will, however, compensate for an inefficient army or navy medical service, and should the War Office or Admiralty be induced by any such expectation to defer the necessary improvements in their medical departments, they will find when the day of trial comes that they have made a fatal mistake. But I shall have to return to this question farther on.

MEDICAL SERVICES OF GERMANY.

Although the arrangements of foreign services cannot be directly adopted in our own, they may teach us how to improve them, for we find most of them imbued with a recognition of the altered conditions of the surgery and medicine of to-day, and making progress in adapting themselves to these changes in a fashion that is not found among ourselves. Much that is instructive may be learned from the medical services of Germany, where, of course, compulsory service exists. In that empire every medical man who has served possesses a fixed military rank, even if engaged in civil practice, and is liable to be called upon to serve where and when required. Those who have not served in the regular army but are in private practice receive annually an inquiry addressed to them by the War Office as to whether they are prepared to serve their fatherland in case of war. Every German medical man who has served in the army at all is maintained for nineteen years under military orders — that is, he possesses a fixed rank, and is allotted, even in time of peace, a known military post which he would occupy if war broke out. Thus the university professors hold high military rank, corresponding with their eminent civil position and scientific attainments, and are required to give annual courses of instruction to the medical officers serving in the army or navy. Such well-known surgeons as Bergmann, Bruns, Trendelenburg and Mikulicz have to teach these classes during the Easter holidays, so as not to interfere with the winter and summer sessions of the universities. Each professor has his fixed military rank assigned to him in case of war; most of them rank as lieutenant-generals, some as generals, and even higher, and in the event of war they act as consulting surgeons to the medical officers of the army in the field or base hospitals. They receive the same pay as the military surgeons, as do also the other surgeons who are liable to be called out in case of war; and some of the latter have places assigned them in the sanitary corps, etc., so that their skill and experience are utilized in every department of the service.

In time of peace German army surgeons have the development of their professional culture ensured by the following measures: The most promising surgeons and assistant surgeons are sent to do duty for a year at a time in the medical, surgical and gynecological departments of the hospitals connected with the universities, and in other large public hospitals unconnected with them. The junior and assistant surgeons are also annually sent to attend the special courses of instruction in anatomy, surgery and operative surgery mentioned above. The senior medical officers nearly corresponding with our surgeons-major, at least the most competent and promising of them, have to serve in rotation in the large military hospitals, in which are treated not merely soldiers but all kinds of ordinary patients; there they have to act as teachers and attend and take a share of the tutorial work among the pupils in the classes of the various professors; or they may be sent to do duty for a year in the general hospitals, not only in the surgical but also in the medical and gynecological wards. They have also to attend, as they may be ordered, annual courses of bacteriology; or they may be furnished with funds for travelling in other countries and studying their medical and sanitation arrangements.

All surgical instruments and appliances in the German army are provided by the State, and in their navy this is likewise the case; every hospital in which the medical officers serve has its complete armamentarium provided for it, so that no unwise economy hampers the most thorough and modern practice of the healing art; and the same thing is true in regard to their naval medical service.

MEDICAL SERVICES OF RUSSIA.

In the Russian army and navy similar care is taken of the professional culture of the medical officers. Russia possesses 6 large and 300 small hospitals connected with the army, besides smaller lazarettos; and in some of these the equipment is far in advance of anything the services possess in this country. Thus the military hospital of St. Petersburg, wherein are treated all medical, surgical, gynecological, ophthalmic and other diseases, consists of five separate clinics or infirmaries, each of which is complete in itself, and possesses departments for every class of disease, and even wards for paying patients. The wards are excellent, and replete with appliances of every kind,

and there are bandage-rooms, purifying-rooms, operation theatres, bacteriological departments, rooms for physical research, laboratories for teachers, and laboratories for students, all excellent and complete. Each clinic possesses 850 beds, 120 of which are for women's diseases, and 20 for children's; and about 45,000 patients are treated per annum. In these clinics the students and assistants have to work in the most thorough manner, and study every kind of case.

The hospital possesses a staff of 34 professors, 70 *privatim docentes* and 47 assistants. Each department is furnished with an ample annual allowance for instruments and apparatus, and can apply for and obtain additional grants for anything more that is required, or for anything new and expensive. They have liberal provision of everything calculated to assist the most advanced work and investigation: x-ray rooms, photographic-rooms, electrical-rooms, immersion lenses, centrifuges, etc., to an extent that excites the marvel and envy of British visitors. The work in the wards, such as case taking, temperature recording, and every sort of examination and study of the cases, is of the very highest character, and the operations and dressings are carried out by the surgeons and qualified assistants in a fashion that is above praise.

Russia has 3,000 surgeons in her army, and any of these may, if he show ability and powers of work, apply for and be ordered to return to study in the hospitals for a period of two years. There he has to work as a regular assistant, and on proving his capacity may attain a place among the teachers of the institution; or he may be transferred to the hospital of some provincial city, and there continue to perfect himself in his profession, and further qualify himself for his duties in time of war.

The Russian naval hospitals are arranged like their army hospitals; they exist in many parts of the empire, there being five large ones at different ports, besides one or two smaller ones; they admit civil cases of all kinds; and in them the medical officers possess opportunities of training themselves in all manner of high-class professional work. In the Russian navy the medical officers who show ability can obtain permission to return for two years to the hospitals, and can there advance by merit, ten every year, to become *privatim docentes*, and so proceed to the position of professor. And they have the same privilege as those of the army of obtaining, after ten years' service, two years of study-leave in the hospitals and schools, during which time they are granted extra pay.

The Russian State supplies its army, its navy, and their hospitals with instruments of the newest construction, embracing appliances for special diagnosis and treatment; the operation instruments, and even the boxes that contain them, are arranged so that they may be readily sterilized by heat or otherwise, and Schimmelbusch's sterilizers and apparatus specially constructed for carrying out antiseptic and aseptic treatment under the difficulties of a campaign are supplied with them. The drugs are prepared for the services in the form of tabloids, with the active principles accurately dosed and made up by the newest machinery. Dressings, bandages, and such like are prepared, sorted, made up, sterilized, and sent out from factories which are ideals of purity, ingenuity and care, in a way that is an example to the world.

MEDICAL SERVICES OF FRANCE.

In the French army, post-graduate courses expressly for medical officers are conducted by professors at the different universities throughout the Republic, and the cost is borne by the Army Medical Department; while a certain number of the medical officers of the active and reserve army are every year ordered to attend them, extra pay being drawn by those who do so.

A SCHEME OF REFORM.

But enough has been said to show that we have much to learn from foreign countries; that, unless we follow their example, our officers, soldiers, and sailors who may be wounded in war will be attended to in a very imperfect fashion compared with those of other European Powers, and that our services stand in need of great reforms, which must be more or less of the following nature.

It would, first, be a great advantage to the services were a section created for military and naval surgery at the annual meetings of this Association, in which all professional matters connected with them could be discussed, and where all communications should be privileged. There can be little doubt that the responsibility for the defects of the services chiefly lies in the apathy and ignorance of the civil part of our profession regarding them, and this is the first thing that should be remedied. Such a section would furnish instruction as to the actual state of matters and what amendments are required, and by its agency the profession and public would be educated to obtain them. Reforms so initiated and urged on the authorities by the Association could not fail to be quickly introduced. In such a section also questions of ambulance, transport, equipment, wounds, and subjects of a kindred nature would be perennially dealt with. And special work by medical officers would secure due publicity and appreciation.

Information as to the condition of the services should be laid before the War Office and Admiralty, and the necessary reforms urged upon them in all proper ways, in order that their organization and equipment may be modernized. The War Office in particular should be induced to carry into complete effect the system initiated when the regimental system was abolished. Medical provision should be made for three complete army corps. This, if it exists at present, is a mere framework on paper, of no real use in so complex a machine as the Royal Army Medical Corps. The number of those who are to serve when war breaks out should be completed; the equipment and materials should be ready and at hand, and men and officers frequently trained in their use.

Field hospitals should have their equipment complete, and their staff ought to be attached to them.

The whole service should be organized as a body of independent units, capable of acting alone or being combined or brigaded as required. Everything belonging to each unit, even to its transport, should be complete and under the command of its medical officers. This would give the military authorities a medical corps on which they could always depend, out of which they could be supplied with

such a proportion of units as the particular exigency required, to be distributed where and when they were called for. Such a system would throw responsibility for the adequacy of medical arrangements on those in command, and we should no longer have the Army Medical Corps bearing on its shoulders a vicarious load of sins whenever a general,— to use a terse vulgarism,— miscalculates the size of his butcher's bill.

INSTRUCTION OF OFFICERS.

The most clamant of all reforms is provision for the proper instruction of officers in their war duties. It is the climax of unwisdom to deny them this, and not until it is fully conceded can the services regain their lost popularity and attract such graduates as will provide the number and quality of medical officers the country requires. The principle of study-leave has been conceded, but cannot be carried out in a service too undermanned to do its work. And the amount conceded is, in my opinion, far too little to enable medical officers to keep pace with the advances of science. I cannot put too strongly the absolute necessity for at least one out of every five years of service being devoted to this. Were every meritorious officer, especially if he have been stationed abroad, set free to devote every fifth year or its equivalent during the first twenty years of his service, or up to forty-five years of age, to visiting and participating in the work of military, naval, and above all, civil hospitals and schools of medicine, much would be done to ensure his possessing the skill in the higher methods of surgery and medicine to which he and those under his charge are entitled to lay claim. In this we should be but adopting what has been found indispensable by other European Powers. Officers receiving study-leave should be sent to act as assistants, residents, and house-surgeons and physicians to our hospitals and schools of medicine, in the same way as our younger graduates who are in training for the highest places in the civil profession. Officers from the services would be cordially welcomed in such institutions, where men of their stamp are continually in demand. There exist, besides, numberless infirmaries throughout the country unconnected with schools of medicine, where most excellent surgery is being daily done, in which they would be received with open arms and welcomed to take a share in the work. It is often most pitiful to see our graduates in the services returning to the schools where they were trained, longing for and acutely feeling the need of such work and practice, who, under existing arrangements, can only hang about for a few days and look wistfully on under every discouragement of their natural aspirations, till they have to turn away, hopeless of obtaining the privilege of mixing among the workers and training themselves in the refined surgery of to-day.

DEVELOPMENT OF HOSPITALS.

It is of the most vital importance that the development of military and naval hospitals should at once receive the attention of the authorities. The services can never be what they should until their hospitals and lazarettos, both at home and abroad, are multiplied, improved, and cherished into new life and activity. They should, wherever it can by any possiblity be done, be thrown open for the reception of ordinary patients from the civil population, and for the admission of diseases of all kinds. The number of medical officers in charge of or serving in them should be largely increased, and they ought to be provided in them with fully the same opportunities as are enjoyed by their civil brethren. No more deadly injury has ever been done to the medical services than by starving and neglecting their hospitals. They are the heart of the services, and it is necessary that the authorities should be brought to recognize that this is so, and follow the wise example set by foreign nations.

HOSPITAL SHIPS.

I cannot believe it possible that the medical arrangements on board our ships of war should be permitted to continue in their present state. The succor of the wounded in a naval action is, no doubt, a question of very great difficulty on board ship, and no considerable alteration of the existing distribution of space can be claimed with any hope of its being conceded. But, without going so far as this, it is the duty of the State to provide those who shed their blood in its defence with suitable special accommodation in as safe a situation as possible, and to see that those in charge of them are furnished with every material, appliance or instrument that can lessen suffering, or confer an additional chance of saving life. Other Powers are more generous and wise, and a nation depending on its navy as we do cannot be pardoned for such suicidal economy.

New discoveries may possibly some day alter the conditions of naval warfare; but in the meantime it seems unlikely that any great change can take place in the general character of our fleets and warships, and a considerable naval action would certainly at present furnish such a mass of wounded men as might defeat the best efforts of the Naval Medical Service to cope with. The only means of doing so, and one so obvious that it is a marvel our country has not long since adopted it, is to provide every fleet with a certain proportion of fast steamers, without armor or armament, flying the Red Cross flag, fitted up with wards, operation theatres and dressing rooms, anesthetic, sterilizing and apparatus rooms, officered by a staff of surgeons and attendants, and in every way imitating the arrangements of the best civil hospitals. These should form as essential a part of every squadron as do the bearer companies and field hospitals of an army. Their duty should be to dash to the aid of ships disabled or out of action, or the moment the conflict was over; and with the help of their trained attendants and the best forms of slings, litters and barges remove the wounded to the protection of the Red Cross, and render them the same attentions as those given in like straits to the injured and wounded in the army or in civil life. The cost of such vesselswould be small compared with ships of war, and the good they would achieve in great naval engagements, and even in ordinary times, would be unspeakable.

I am glad, since this was written, to perceive that the Peace Conference at the Hague has occupied itself with this question, and is endeavoring to secure such vessels being treated as neutrals. But, even if the Conference fail to procure their neutrality, it will not make it the less our duty to provide such vessels in the navy.

CIVIL AID A BROKEN REED.

It is necessary, also, to make strenuous war on one of the most serious obstacles in the way of obtaining the reforms required for perfecting the services — namely, the tendency on the part of the military authorities to believe that deficiencies in them can at any time, by the power of money, be compensated by engaging civil aid. No more erroneous idea could possibly exist, as those who are acquainted with its working well know. The civil aid at present employed in various stations throughout the country is of an inferior quality, and could not, even such as it is, be made use of in war to any extent. The medical men who fill these substitutive posts, as well as those who would volunteer to aid in active service, are not the skilled and trained class who could be entrusted with the difficult surgery of gunshot wounds. The urgency of the situation has driven some to suggest that should need arise, the duty of attending part of the wounded and convalescents could be discharged by existing civil institutions. This could never be the case to any extent; neither their accommodation nor funds could be made applicable to such purposes, save in the event of a dangerous national crisis. The country and the heads of the services must be brought to recognize voluntary aid, even such as that proposed to be organized by the Central British Red Cross Committee, cannot provide the class of medical officers required, unless that organization were to be developed at great cost into a second army medical department, which would crush the present one out of existence without being itself fitted to take its place. The fatal error of imagining that the Army Medical Corps can be supplemented by civil aid is one that has already done infinite harm; it has been made a constant pretext for hindering the due development of the services and producing the defects of which I have spoken, and is a mischievous delusion that cannot be too strongly combated. Were such a proposal made regarding any other scientific department, such as, say, the royal engineers, its absurdity would be at once perceived; but so little is the peculiar position of military surgery known to the laity that it passes as being reasonable among many without, and some even within, the limits of the medical profession. At its best it is but a poor palliative, but can never be a cure.

FALLACIES AND FACTS.

It is conceivable that some may be found, even in the services themselves, who contend that they are not in so unsatisfactory a condition as I have painted. They can point to good work done in them but yesterday, to individuals in them whose admirable labors or brilliant achievements are well known to us all, and to evidence that special institutions or special expeditions are provided with many of the latest appliances for scientific diagnosis, treatment or research. It would be wrong to deny, or grudgingly and unfreely to admit, these facts; to overlook the enlightened, devoted and admirable work, or the talents and valor of numbers of our brethren in the services; or to minimize the efforts of those highly placed in them to maintain and elevate their standard. I should be be very sorry to seem to do so. But let those who hold that all is well with the services visit the hospitals, depots, ships and stations of the army and navy, and see with their own eyes the circumstances under which the surgeons have to work now, and would have to work in war. Let them contrast their equipment with that of our civil hospitals, even of our minor country infirmaries. Especially let them study the military and naval arrangements of other countries, and realize the full and energetic professional life enjoyed by the medical officers of the best European Powers. They will then find no escape from the conviction that our present system is most seriously at fault, and that without recognition of this and its timely amendment our country will have its eyes rudely opened when the strain of war shall arrive, and the test of facts unfolds the lamentable revelation of how unfitted the services are for their great and real work. I have given sufficing reasons why I and many civil surgeons feel unable to agree with those who take a hopeful view of the condition of the services, and have striven to show that there lies before us a struggle of no small magnitude to be gone through ere we can expect to do so.

I trust it is not necessary for me to say that, under what I have stated regarding them, there lurks no hostile undervaluing of the services, or of those who are in their ranks. I have been moved by a sincere respect for them, and regard for their interests, and by the conviction that the present is a suitable time for one in the civil part of the profession to speak boldly what is in the minds of many civil surgeons, and is known to still more who are in the services themselves. "Better are wounds from one who loves than fraudful kisses from an enemy." It has been far from my intention to reflect on the medical officers of the army and navy, numbers of whom are my own intimate and valued friends. Should I seem to have done so in any degree, then:

> **Sir, in this audience,**
> **Let my disclaiming from a purposed evil**
> **Free me so far in your most generous thoughts,**
> **That I have shot mine arrow o'er the house**
> **And hurt my brother.**

I know well that though in the services good work gets little reward, and bad work as a rule no punishishment, yet in truth there is much good work done and little bad. I have been privileged to witness those in them doing all that men can do under the most discouraging circumstances, where everything seemed to conspire against success, and have admired and wondered how well things were done. The system is at fault, not the men, and no body of men can quite overcome the impossible conditions in which the services are placed, or make bricks without straw.

But I hope my motives will not be misjudged, and that what has been said may contribute in some degree to stir the profession generally, and this powerful Association in particular, to increased efforts to open the eyes of the British nation to the real state of matters, regarding which it is at present blind; so that when the Temple of Janus once more opens in our midst, the services may be found in such a state of preparation and efficiency as is demanded by the honor and well-being of our country and the interests of humanity.

Illegitimate Births in Munich. — Of the 16,234 births in Munich last year, 28.6% were "out of wedlock." And yet the German papers glory in the fact that one-third of the births in Paris are illegitimate. — *Philadelphia Medical Journal.*

POTT'S PARAPLEGIA AS AFFECTED BY THE CORRECTION OF THE SPINAL DEFORMITY: A REPORT OF CASES.[1]

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

Until the past two or three years the commonly accepted treatment of Pott's paraplegia consisted of rest in bed with as thorough fixation of the spine as was possible, together with the less common but frequent use of traction and counter traction.

The duration of the paralysis varied with the location of the disease and the age of the patient. Rarely did it disappear before six months and that in children, while in adults few recovered in less than eighteen months or two years. In a certain number of cases, even after a longer period of time, and even under the most careful treatment, the power failed to return. This has formerly been considered to be due to degeneration of the cord, and consequently it was supposed that the condition was hopeless.

Various theories have been offered in explanation of the paralysis, such as abscess; direct pressure of the softened vertebra upon the cord; pressure due to a tuberculosis of the meninges; the tubercular process extending into the cord itself, involving the interstitial tissue surrounding the nerve fibres; an edema of the cord due to imperfect circulation at the seat of the disease, and probably others which have escaped my notice or memory.

As the result of the work which has been done during the past three or four years in connection with the correction of the spinal deformities, the course of the paralysis has been changed in so striking a degree that it becomes necessary for us to reconsider some of our former views, and it may be possible by studying a group of such cases to speculate more definitely upon the exact etiology of the symptoms.

The most striking fact in treating these cases is that whatever the etiological factor may be, the correction of the spinal deformity, or only a partial correction of the deformity, has been followed by a very rapid and at times an instant relief from the paralysis. This result has been so universal in my own experience and so common in the hands of others who have pursued the same method that, while at first the disappearance of the paralysis was supposed to be only a coincidence coming in connection with the correction of the deformity, at present the correction of the deformity has come to be of secondary importance to relief of the paralysis which is to be accomplished in this way.

In my own experience of the eleven cases which have been treated in this way all have shown a marked improvement in the motor control of the legs within a few days of the time of treatment. In some of the cases, either because of the location of the disease and the inability to hold the spine in the corrected position, or because of inability to control the after-treatment, it has not been possible to make the improvement permanent, and relapse has occurred. The fact, however, that the paralysis has been relieved by the change in the position of the spine has been demonstrated, and the demonstration repeated several times in one of the cases.

Of the eleven cases, five were reported at the last meeting of this Association in the paper entitled "Forcible Straightening of Spinal Deformities resulting from Pott's Disease," and they are again mentioned because the subsequent history of the cases is of fully as much interest as the immediate result.

Of the eleven cases three were children; of these one with disease in the upper lumbar region was entirely and almost immediately relieved by hyperextending the spine. Ether was not used, and after one year, during which the position of the hyperextension has been maintained, there has been no return of the paralysis. In another child, with disease of the first and second dorsal vertebra, the weight of the head alone was not enough to correct the deformity, so that ether was used for this purpose. This was followed by marked improvement in the control of the legs, but the improvement lasted but a few days only. The treatment was repeated once or twice with the same result. Each time the paralysis was relieved, but the improvement lasted for only a few days, the relapse being due undoubtedly to the inability to maintain the corrected position because of the location of the disease. The child is none the worse for the treatment, and is now being treated as formerly in bed with immobilization of the spine. The third child, with a large deformity in the mid-dorsal region, and with complete paraplegia, was considerably improved by the improved position of the spine, but the improvement has not been permanent.

Of the eight adult cases five were men. The oldest patient was a man of forty-three years of age. In only one of the cases was ether used, and this was one of the cases before the apparatus which is now in use had been perfected. At the present time I feel sure that even in this case ether would not have been necessary.

Of this group of adult cases, one of the most suggestive and interesting from a physiological as well as a pathological point of view is the case of the man of forty-three years of age. In this case the disease of the spine had been present for about six years. During the first part of the time he was under my care at the Carney Hospital, but paralysis developing, and having no home, he was sent to the Almshouse Hospital at Long Island, and there he had lain for four years previous to the commencement of the present treatment. While at Long Island he was under the care of Dr. E. W. Taylor, and it was through his kindness that it was possible for me to see him. The knuckle was in the mid-dorsal region, and there was, with the exception of as light tremor in the three middle toes of the right foot, absolute paralysis of everything below the waist, together with a partial paralysis of the bowel. The knees and ankles were stiff, while the feet were not only stiff but were fully extended so as to be in a straight line with the legs instead of at a right angle to them.

The patient was transferred to the Carney Hospital in July of last year, and a plaster-of-Paris jacket applied, with the spine in the hyperextended position. In a few days he could move the toes of both feet, but because of the long disuse the cerebration was uncertain for some time, and when asked to move the right foot, the left one was perhaps the one moved, and *vice versa*. This gradually improved, however, so that later the cerebration was in no respect peculiar.

Since July jackets have been applied about every six weeks, so that the spine has been kept constantly

[1] Read at the meeting of the American Orthopedic Association, held in New York, May 31, 1899.

hyperextended. Ether has been used but once, and that not for the spine but to free the contractions and adhesions about the knees and at the ankles. There has been a gradual improvement in the voluntary control of the muscles of the legs, so that at the present time there is a response in practically all. The improvement has naturally been slow, as after four years of absolute disuse the muscles had undergone the most extreme atrophy. The rectus femoris, for example, was at first represented under contraction by a small band not wider than one's finger and not as thick, while at present, even though it is still very small, it has developed sufficiently, so that when the knee is raised, flexing the joint thirty or forty degrees, the patient is able voluntarily to lift the leg from the bed and straighten the knee.

At the present time the patient is able to stand with the aid of crutches, and by being steadied can swing himself along the length of the ward.

The case is of interest even though there be no further improvement, which is possible, as he has recently developed tuberculosis of the genito-urinary tract, as it demonstrates that the function of the spinal cord can be wholly arrested for at least four years and still retain a portion, at least, of its power of transmitting impulses.

Of the other cases, one of especial interest is Case IV., a young woman twenty-one years of age. Paralysis had been present for about eighteen months, and the disease for four years. The patient was first treated in January, 1898, with almost instant relief from the paralysis, so that in one month she was walking about. She then became and has since remained an out-patient, reporting about once in six weeks to have the jacket reapplied. The point of special interest is that during the extreme heat of last summer her request to have a removable jacket was granted, the understanding being that the jacket was to be opened only when lying down. One week from that day the patient was brought to the hospital with paraplegia. She was sent to the ward, and a fixed jacket applied the following morning. As soon as she was put in position on the frame, no force being used other than her own weight, she remarked, "Now my legs are all right." The jacket was applied and that afternoon she left the hospital walking as well as ever. There has been no trouble since except once when the jacket had softened considerably the legs were said to feel weak and unsteady. The new jacket entirely reli-ved this sensation.

In two of the other cases there has been a temporary return of the paralysis due to the softening of the jacket, and in both cases the condition has been relieved at once by the correction of the position of the spine in applying a new jacket.

The following case is mentioned rather more in detail, as it represents a somewhat different condition, and the marked improvement which followed the treatment was more unexpected than in the other cases. With this one exception the cases which are here reported had developed the paralysis in connection with the acute or active stage of the disease. In this case, however, the active disease in the spine had occurred many years before, the spine probably having become anchylosed in the position of extreme deformity. In such a condition naturally very little was expected as the result of any attempt to correct the position of the back, the paralysis presumably being due to a late suppurative process developing in the rigid canal and thus causing pressure. The actual result, however, in this case was equally as striking as that obtained in the others. The paraplegia was much lessened by the application of the first jacket, and after the last one, which represented the third jacket, she was able to be up and move about. In this case the sensory paralysis which was present was likewise relieved.

The cases in detail are as follow:

CHILDREN.

Case I. W. A., a boy eight years of age, with disease of the upper lumbar spine of two years' duration. Paraplegia developed one year ago and was entirely relieved by hyperextending the spine without ether. Plaster-of-Paris jackets have been worn since then, the same position of the spine being continued. There has been no return of the paralysis as far as the motor central is concerned, but the knee reflexes are more lively than normal. There is no ankle clonus or noticeable weakness of the legs.

Case II. J. F., a boy six years of age, with high dorsal caries of one year's duration and during that time he had been under treatment with the usual braces. A few months previous to the time of the examination the patient developed complete paraplegia. Ether was used and the spine straightened, with marked relief, so that the child was able to move the legs about quite freely. In a few days, however, the paralysis returned, owing probably to the location of the disease and the inability to hold the spine hyperextended. The same manipulation was attempted two or three other times, and each time there was the same improvement, but also the same relapse in a few days. The child is none the worse for the treatment, and at present is being treated by recumbency with as thorough fixation as is possible.

Case III. R. L., a girl eight years of age, with Pott's disease of three years' standing, and quite a marked knuckle. She was treated at the Good Samaritan Hospital. Several attempts were made without ether to hyperextend the spine by both Dr. Thorndike and myself, and while two of the attempts at least were followed by improvement, it was of but short duration. At present the paralysis is the same as before the treatment was begun.

ADULTS.

Case IV. K. St. J., a young woman twenty-one years of age, with Pott's disease of four or five years' duration. There was a marked deformity, and paraplegia had been present for nearly two years previous to the time of the correction of the position of the spine. Ether was used and after the correction a plaster-of-Paris jacket was applied. The paralysis was relieved at once and there has been no return, except once when the jacket was partially removed at home, and once or twice when the jacket has softened. At each time the correction of the position and a new jacket has relieved the trouble. The knee jerks have remained much exaggerated. There is no ankle clonus and the voluntary motor control is normal.

Case V. T. D., a man twenty-one years of age, with disease in the mid-dorsal region of two years' duration. Paraplegia, in which the bowel also was involved, developed twelve months ago. The position of the spine was corrected without ether with instant relief of the paralysis. An abscess has developed since

the treatment was commenced, but there has been no further trouble from paralysis either of the legs or bowel, except once when there was a slight temporary return due to the softened jacket. A new jacket entirely relieved the difficulty. The knee reflexes are still exaggerated.

CASE VI. H. G., a man twenty-eight years of age, with disease in the lower dorsal region of two and one-half years' duration. Paralysis had been present with the bowel also involved for six months prior to the treatment. The correction of the position relieved the paralysis at once and there has been no trouble during the past year, except slight temporary trouble when the jackets have softened.

CASE VII. A man thirty-six years of age, with mid-dorsal Pott's disease of comparatively short duration previous to the time of the first examination in April, 1898. At that time there was also disease of one knee-joint. The treatment for the spine was imperfectly carried out, owing to the fact that the patient lived at a distance from the city, but with the one jacket with an improvised apparatus there was a marked improvement in the motor control of the legs. The treatment was discontinued and the paralysis returned.

CASE VIII. T. M., a man twenty-nine years of age, with disease of the mid-dorsal spine of five years' duration. At the time of the first visit at the Carney Hospital in January, 1899, there was well-marked paraplegia. This was entirely relieved by the application of a jacket in the hyperextended position, and there has been no trouble but once when the jacket had softened.

CASE IX. T. D., a woman thirty-two years of age, with disease in the upper lumbar region of two years' duration. Paralysis had been present for about three months previous to her admission to the Carney Hospital four weeks ago. A jacket was applied in the hyperextended position and there has been a steady improvement, so that the patient is now able to walk about.

CASE X. P. M., a man forty-three years of age, with disease in the mid-dorsal region of six years' duration. For four years previous to beginning the present treatment he had lain on his back in the Almshouse Hospital at Long Island (Boston) with absolute paralysis of both legs from the waist down, together with paralysis of the bowel. It was through the kindness of Dr. E. W. Taylor that I was able to see the patient. Nine months ago he was transferred to the Carney Hospital. At that time there was absolutely no voluntary muscular movement below the waist except a slight tremor in the three middle toes on the right foot, and this was so slight as to escape notice unless carefully looked for. Both feet were fully extended at the ankle and were rigid, partly due to joint adhesions, and partly to muscular stiffness. The knees or hips also could not be bent. The legs were edematous, and the circulation as shown by the condition of the skin was very poor.

Without ether the spine was hyperextended and a jacket applied. Within a week there was distinct voluntary movements in both legs. A few weeks later, under ether, the tendo Achillis were cut and the joints of the legs manipulated.

Until four months ago the patient made a steady gain, so that there was a voluntary reponse in practically all of the muscles of the legs. At that time a tubercular process developed in one testicle, necessitating surgical interference with a temporary discontinuance of the treatment for the back.

For the past three months the spinal treatment has been continued, together with the manipulation of the legs, and even though there are some signs of tubercular process higher up in the genito-urinary tract, the improvement has gone on so that there is strength enough in the anterior thigh muscles to raise the foot from the bed and straighten the leg, when the knee had first been flexed and supported. With the aid of crutches and an assistant to steady him he is able to walk the length of the ward. The improvement has been so steady that were it not for the manifestation of the disease in the other organs I feel very sure that he would be able ultimately to go about independently.

CASE IX. Miss E., a woman forty years of age, with a large rounded kyphosis involving the mid-dorsal region, which had developed over twenty years before.

In 1892 there was an attack of paraplegia lasting for three months. In September of last year the paraplegia again developed with sensory disturbances. The reflexes were extremely exaggerated and the voluntary motor control entirely lost. The patient was seen in consultation with Drs. S. A. Lord and C. F. Painter.

A jacket was applied with the spine hyperextended as much as possible, and since then three or four other jackets have been used. With each the paralysis has lessened, so that at present the patient is able to walk about freely.

The apparatus which was used to obtain the desired position of the spine was described and pictured in a paper read by me before this Association at the meeting held last year, and afterwards published in the *Boston Medical and Surgical Journal*, July 28, 1898.

A HOSPITAL CLEARING HOUSE.[1]

BY CLARENCE J. BLAKE, M.D., BOSTON.

WITH the aggregation of population in cities, the multiplication of facilities for suburban transportation and the growth of urban hospitals, there comes more and more urgently to the administrators of trusts for medical relief the question of making such provisional classification of applicants, in out-patient departments especially, as shall assure to the worthy poor, for whom these institutions are principally maintained, the full meed of time and attention which is their due.

From a business standpoint the hospital may be defined as an institution in which capital and skilled labor combine to provide such members of the community as are temporarily disabled and without means of support with the maintenance and care which shall fit them to become again self-supporting and active community factors.

The hospital is a free repair shop for human machines and the capitalist who contributes to its support does so with the basal, though perhaps not with the defined, understanding that his contribution is returned to him through the community in the lesser number of incapacitated and dependent machines; while the doctor, who furnishes the skilled labor contribution, finds his return not only in the same manner as the capitalist citizen, but also in many other ways which

[1] Read before the Massachusetts Medical Society June 14, 1899, and recommended for publication by the Society.

need not be enumerated before this Society and which enure greatly to his own well-being and usefulness.

It is incumbent upon both these contributors to see that their contributions are justly disposed.

The ability to contribute in itself constitutes a trust.

It will be seen that the foregoing statement leaves out of consideration many of the motives which have led to the foundation of and continuance of contributions to the support of our hospitals; not that these motives, or the sentiment underlying them, which is the vital stimulus of all human brotherhood, is decried, but that the care of and provision for the needy sick is so serious a business as to demand the best judgment we are able to bring to bear upon it, and often the fittest use that we can make of a cherished sentiment is to split it into kindling-wood and with it start the fire in the harder fuel of our best endeavor.

Setting aside the emergency cases, whose urgent need of help is paramount to every other consideration, the applicants for hospital relief whose pecuniary fitness has to be considered are broadly divisible into two classes: (1) Those taken into the wards for more or less continued treatment as inmates; (2) ambulant cases; patients who, residing in their own homes, come to the hospital for occasional or for daily treatment. The latter make by far the greater number, and it is in response to their needs that the so-called out-patient departments of our hospitals have grown to their present dimensions, and have come to require administrative effort in classification far beyond anything that would be needed in a hospital receiving house cases alone, for with a patient admitted to the house there is usually ample opportunity for leisurely investigation.

That the sifting-out process in the admitting room of the out-patient department of a large hospital, however, is one which must be done with precision and celerity is shown not only by the large number of ambulant patients applying for relief but by the number of sub-divisions which must be made in order to secure to the eligible patient in the waiting-room protection not only from the presence of contagious diseases but from the encroachments of those pecuniarily unfit applicants, who, either through ignorance or guile, rob not so much the institution and the doctor as the really needy.

The "pecuniarily unfit" cases in out-patient departments in large cities may be generally estimated to constitute from five to ten per cent. of all patients applying for treatment and they may usually be classified as follows: (1) Persons ignorant of hospital usage and both able and willing to pay for professional services rendered; (2) persons who by a pretense of poverty seek to procure medical services for which they are able to pay; (3) the class of persons known in institutions' departments as "rounders," people who go from one hospital to another seeking advice and treatment, a species of medical mendicants; (4) persons who are able to pay a small fee but who are sent to the hospital by their family physician instead of being referred to an individual practitioner.

That the people who come under these four classes should be allowed to share indiscriminately with the proper objects of charity the hospital bounty is a lapse of justice in two directions, justice to those who support the hospital for a definite charitable purpose and justice to the doctor and the patient, for, with the large number of truly worthy patients, the time which the doctor can afford to give to the hospital is none too much to be divided among the many, and with the increasing difficulty of gaining a remunerative foothold in private practice the doctor, and especially the younger doctor, should have the fee, however small it may be, which the patient is able to pay for service rendered.

Various suggestions have been made as to the best method of dealing with the "pecuniarily unfit;" one, that an already existing institution like the Associated Charities should be asked to establish a department or to use some of its already operative machinery for the investigation and detection of these cases; another, that the doctor who treats the patient in the hospital out-patient clinic should himself question the patient as to his pecuniary condition.

To this latter proposition there are two very evident objections, namely, that the process of questioning takes time which properly and under the rules of the hospital belongs to the worthy patient, and also that there should be no connection whatever between the private practice of the physician for which he is paid and the practice in which he gives his services under the auspices of the hospital of which he is one of the recognized staff.

Against the first proposition it may be urged that while the Associated Charities organization and its records may be occasionally availed of, the duty of protecting their dependents and patients belongs properly to the hospitals themselves, either individually or both individually and through the medium of some organization in which they shall all have part and to the support of which they shall all contribute.

The extent to which individual supervision is exercised in this city and the opinions in this matter of those having hospital administration in charge are perhaps best set forth in the following communications.

The first is a letter from Dr. Farrar Cobb, Superintendent of the Massachusetts Charitable Eye and Ear Infirmary:

DEAR DR. BLAKE: — You asked me to write you in regard to the system in use at the Infirmary with respect to weeding out unfit cases. Allow me to say in the first place that it is very exceptional for any but poor and needy patients to obtain admittance to the wards of the Infirmary. The questioning and investigation of all the cases recommended for admission to the hospital is especially thorough, and after careful observation of the inmates of our wards for a long space of time, I am convinced that it is rare to find a patient who is not deserving of the charity of the Institution. There have been, however, occasional instances of deliberate misrepresentation, and consequent admission to the hospital, but such cases are very rare.

In regard to the attendance in the Out-patient Department, we have for three years carried out the following method: The registrars in the Out-patient Department are instructed to question any case which they think from appearance, or address, or occupation is able to pay a physician two or three dollars, and call attention to the fact that the Institution is only for the needy poor. In some instances each day it is necessary to send troublesome cases to the executive offices, and have them more carefully questioned. The limit of our questioning is to ask a suspected case whether he is willing to sign an affidavit that he is an object of charity. If the answer is yes, no further questioning is done. The registration slips of each case that has been questioned at the office are stamped with one of the two rubber stamps which I enclose,[2] and put on file in the records. The system as it is now working is not

[2] "This case was unfit and therefore was refused treatment;" "This case has been questioned at the office and is a suitable case."

very successful. I have no doubt that a considerable number of unfit cases receive treatment each day in our Out-patient Clinics. It is my wish within a week or two to put one of my best and most responsible clerks in charge of a *special inquiry* room in the Out-patient Department for two hours each day, and to have all cases suspected to be able to pay sent to him for thorough questioning.

One thing that I especially object to on theoretical grounds is the questioning of the patients by the doctors themselves, especially in the presence of other patients. I am decidedly of the opinion that such practice is wrong, and liable to misinterpretation. Investigation and questioning should be done by the executive department through some responsible agent. As I said above, now that our new Infirmary is running successfully I hope within a week or two to make a radical departure in the line suggested. Yours very truly,

FARRAR COBB.

At the Boston City Hospital, the out-patients are refused treatment by the physician in charge of the department at which the patient applies if the physician thinks the case in question unsuitable for charity.

If the patient insists upon being treated after being refused treatment upon the grounds of pecuniary unfitness the question may be referred to the Superintendent for futher investigation and decision. In the eye department there is a rule that the patient asking for a prescription for gold-rimmed glasses shall be refused treatment on the ground that the ability to afford this luxury implies ability to pay a physician. Dr. Rowe may be quoted as saying: "I do not believe that abuse can be stopped until all hospitals in all cities agree on some simple rational system and live up to it."

At the Massachusetts General Hospital all new out-patients are seen by the admitting physician and questioned as to their ability to pay for medical treatment, unless their appearance evidently indicates that they are suitable cases for charity; patients who admit their ability to pay something are refused treatment; those in regard to whom the admitting physician is in doubt are referred to the superintendent for further questioning and final decision.

Patients known to have been treated in other hospitals for the trouble for which they come to the Massachusetts General Hospital are referred back to the original clinic for treatment unless there seems to be a good reason for retaining them.

At the Boston Dispensary all new patients, except such as are evidently charity cases, are questioned as to their ability to pay for treatment. Doubtful cases which it seems best to admit are reported to the physician who is to have charge of the case for supplementary questioning.

In one way or another, therefore, the hospital administrations seek to winnow their applicants at the gate, but the winnowing process is one which lacks uniformity and co-operation and hence fails of the best execution.

The use of the term clearing house in this connection is not inadvisedly made, for in addition to its limited application in the banking system as early as the year 1856 in this country, a clearing house in other lines of business has come to be a central bureau not only for the establishment and maintenance of balances but for such co-operative investigation as may constitute it a bureau of information as well; and it is readily conceivable that the establishment and maintenance by hospitals in a large city of an officer to whom, or a bureau to which, there could be referred, for more leisurely investigation, pecuniarily doubtful cases, would not only relieve the individual administrator of a part of a most unwelcome task, but would in time become a channel through which there should flow interchange of ideas, and from which there should emanate to the public instructive information as to the rights as well as the obligations of hospitals.

Such an officer or bureau constituting a clearing house should be under the direction of a board of control, said board of control being not as is proposed in the new Dispensary Bill of New York, the State Board of Charities, or other alien organization to which is given a dominant power, but a board of control made up primarily of the medical superintendents of the hospitals themselves. A board thus formed and backed if possible by legislative enactment, making fraudulent abuse of medical charity a misdemeanor, would be likely to be an efficient piece of machinery for the attainment of the desired end.

The attention given to this question of the abuse of medical charities in the meetings of the National Association of Charities and Correction in recent years and the agitation accompanying the framing of the Dispensary Bill in New York are among many evidences that this subject is attracting the thoughtful consideration of the public at large, and the conclusion that any carefully-considered remedial measure emanating from medical sources is likely to receive cordial support, is based upon the fact that while the abuse is one which concerns the well-being of the community as a whole, its correction is properly one of the responsibilities of the medical profession.

VOLUNTEER AID WORK IN FOREIGN TERRITORY.[1]

BY ELLIOTT C. BRACKETT, M.D., BOSTON.

In responding to the request of your committee to make a few remarks on the volunteer aid work of last summer, it seemed best to restrict such to some of the general considerations which would suggest themselves from an opportunity of seeing this work conducted under unusual conditions. From this standpoint the position of bodies of volunteer relief, particularly in these days of well-equipped facilities for meeting emergencies, is a question of great interest.

The work of the Massachusetts Volunteer Aid Association of last summer is so well known to you all, — probably the majority of those present were more or less intimately connected with its affairs, — that I do not intend to take your time with the details of any special department. It came into existence with the urgent demand at the time, filled its mission, and then was over. But now that it is a thing of the past, and yet is not too far distant for us to lose the active interest in its affairs and what it accomplished, there is much we can learn from the retrospect of the experiences during this time, and it is my object to briefly consider from this point of view the results of my connection with this Association in its work in Santiago.

Toward the latter part of July the officers of the Volunteer Aid saw the need of having in Cuba a

[1] Read before the Massachusetts Medical Society, June 14, 1899, and recommended for publication by the Society.

representative of the Association, who should have charge of the distribution of the supplies, determine from personal observation what needs of the men at the front could be reached by this society, and act as the representative in its work out of the country. Many supplies which were fast collecting here had already been sent, but they were not in charge of any one, either on the way or after their arrival, and it was doubtful if they would reach their intended destination or receive the proper distribution; and these doubts proved to be well founded, for in the condition of affairs at that period every one had more than enough of his own work to do, and could not be expected to give attention to other affairs requiring so much time and attention. It was this position it became my privilege to take.

The plan was to send such supplies as were at hand to Santiago, to have them distributed directly to the regiments according to the special needs, and to personally determine what might be the special requirements of the men at the time, which could be met by an independent organization. The real state of affairs at this time was, as you all know, much a matter of conjecture. Information was meagre and unreliable, but that there was distress and suffering, and particularly among the men who were not hardened by long training, was certain. It was known that sickness had appeared, and was on the increase, that it was approaching the rainy season, the worst of the year, in a province which had always been infected with contagious disease, and these conditions, combined with the fierce heat of the tropics, and the presence of so many troops crowded together, left no room for doubt of the need of aid in a general way. With these as facts were rumors of scarcity of so many necessary supplies, and although the probable exaggeration was recognized by all, the indication of the need of aid was plain. Until further information could be obtained it was proposed to send such supplies as would be needed by the sick and convalescent in the camps and in hospitals, both in the way of foods and clothing, while the special needs could be determined after arrival, and procured if such were possible.

The problem of reaching Santiago, and in the shortest time possible, was met by the officers of the Association in a fortunate way. At this time the province was closed to ordinary travel, no steamers except a few of the government transports were in this part of Cuba, and quarantine had been declared against the port; therefore it became necessary to reach the destination by an indirect route. Through the courtesy of the Boston Fruit Company the supplies were sent, and I took passage to Port Antonio, Jamaica, one hundred miles south of this part of Cuba, and from thence a small sailing vessel was chartered to complete the journey to Santiago. In this way the errand reached its destination early in August, a little over ten days from the time it was first considered as a plan.

Here, the conditions under which the men had been placed during the previous two months gives one the best idea of the position of an organization such as the Volunteer Aid in its effort to render assistance so far from home, and this applied particularly to the men of the volunteer troops, for whom the work was originally but not solely intended, who had not the opportunity to learn from experience or from training how to save their energy and avoid many dangers under conditions so unusual and trying even to veterans, and who would in consequence suffer more from the results of their exposures.

Without time for acclimation, these men had landed, after nearly two weeks' confinement on a crowded transport, had marched through an unusually rough and hard country, were two days in the fight, and for three weeks immediately following lived in the trenches for most of the time with no shelter either from the sun or the almost deadly rains. During this period they were on the short rations which their difficult position necessitated, and exposed during the day to the intense heat of a tropical midsummer, and at night to the damp chill found in these latitudes. From the time of the surrender of the city they remained camped in the small shelter tents under practically the same conditions. By the early part of August the prolonged exposures, heat, and unusual living had begun to show itself extensively in the very great debility among the men in general, and the breaking out of diseases. Fortunately the most prevalent were the forms of the climatic disorders rather than the contagious diseases, but the effect of this severe type of malaria on the men, already much weakened by the conditions of the previous two months, was much more disastrous than it would have been under any other conditions. There was no provision for the convalescents either as regards place or food, and since the fever usually produced digestive disorders, the recovery was extremely slow and subject to relapses, and this long absence from the ranks threw additional burdens on those remaining well. Added to this physical debility was the uncertainty of their detention on the island and this, with the knowledge that their work as troops was practically over, that they were merely waiting their turn to be taken home, and with the increasing disease which daily thinned the ranks of the men in active service, made the condition seem still more anxious, when the question of prolonging the stay was considered, and this in a city where the usual epidemic of yellow fever was thought by all to have already begun, and with conditions ripe for its development. It was in such a situation, the result of the sudden culmination of events, that properly-directed aid from an independent organization could be of great material help to tide over the emergency, although whatever one branch might accomplish could be but a comparative mite in the presence of such general need. The emergency which the officers in that city had to meet was an unusual one, both in character and proportion. The amount to be done was enormous, the conditions both of place and season difficult to combat, the facilities meagre, and the corps of workers small and already weakened by their hardships. It can be truly said that the improvement which took place, and the low mortality which finally resulted, was due alone to the strenuous efforts of the officials left in charge, in spite of their handicapped position, and of the lack of early aid in the way of suitable supplies and means from headquarters in this country.

In such an emergency the most important needs must receive first consideration, for something must give preference. So far as the troops are concerned, the sick must be attended to as best facilities will allow, the body of troops which make the working force must be cared for, and the convalescent sick must receive later attention. This is not neglect, but the

only solution of the difficulty, and in times like this the independent organizations find their work waiting for them. It is to fill in the gaps which in the sudden emergency cannot be or are not provided for, and from the position far away from home cannot be filled without disastrous delay. The work naturally has but little to do with the well; such is not necessary, and would interfere with the system so necessary to maintain proper discipline.

I shall not enter into the detail of the work of the relief of this department during last summer. It would be enumeration of days of tiresome routine. The character of the work to be done and the direction in which to put it forth was only too evident. It remained only to do what was possible with the limited material and the conflicting circumstances of place and facilities, trusting that the effort would meet with success. Fortunately the stay of the volunteer troops in this section was not prolonged.

The relief work in a territory so remote from any base of supplies must consist in using material at hand to the best advantage; the supply will be short, and economy is necessary. The difficult problem is that of the means of transportation, and the method of distribution, for one ought not depend upon aid from those whom the object of the errand is to help, and who are already overburdened with their own duties of daily routine. The situation shows definitely along what lines the working of an organization of this kind should be carried on without conflicting in any way with the regular service, but rendering its aid where it is needed and welcomed.

The position of relief bodies has occasionally had criticism from various sources, too often, I fear, by those who in the time of stress have received their bounty. The criticism without a doubt confuses the question of the need of the existence of such bodies with the time that their work is needed, for so long as such campaigns as that of the past year are instituted, and so long as volunteer troops are used, there will be a time in campaigns when the work of such bodies will be welcomed to prevent avoidable suffering, and such loss of life as is not an incident to the active part of a campaign, for during campaigns of recent years the usefulness of such work has been shown too clearly, and although now with the advance in the departments of science, which shortens time and space, allowing emergencies to be met with greater ease and promptness, its work becomes more defined but none the less important.

The general operation of an organization of volunteer work in a campaign in foreign territory must be considered from a different point of view, from the distribution of relief at home within easy access of supervision, and of supplies of all kinds. An expedition of invasion would naturally have its own provision for the prevention and relief of these same conditions, and with time for preparation in these days, such would undoubtedly be done, and we may consider that there is a time when there will be the demand for volunteer aid, and such is in the early part of a campaign, particularly if begun as most are, with insufficient time for complete preparation, when the attention of the service is directed to providing for the certain requirements, and the possibilities which pertain to comforts of sick and requirements of convalescents, and of affairs which do not affect the regular service, which cannot receive the same attention, especially when arising from a condition of so complete unexpectedness.

Therefore, the work of such organizations is needed to supply the emergency needs, which take time to collect, and individual attention to properly distribute, and particularly during this early period, when there are conditions to be met which would not be found at a later time, and such was so clearly illustrated in the latter part of last summer. To new men, unused to the hardships, and in the waiting part of a campaign, and of whom it is not asked to become regulars or veterans, the advisability of mitigating some of the rigors of campaign life is evident, rather than sacrifice men to the hardening process, for the sake of the training alone. The situation calls for requirements not provided for in the haste of departure, or perhaps not belonging to the regular service, and in no way is this shown so distinctly as in the case of convalescents. There are some kinds of work, notably among such are those of humanitarian nature, which require individualism, and when carried on by too large organizations lose this essential by too much of detailed duties. Volunteer work also has the advantage of being unrestricted by the slow-acting and cumbersome regulations which are the necessity of a large organization, and is able in consequence to insure that relief may reach its destination promptly, and without the otherwise certain delay. It is necessary that a relief expedition should be complete in itself, that an independent source of relief supply should be maintained, with such provision for its distribution that demands on it can be met without delay. The particular need for this period and for this kind of work is for not only what may be classed as comforts of the sick, but for the more general care of the convalescents.

The method of procedure must vary with the different instances, but the safe rule is to reach the men through official lines, and in the direction indicated by them. In positions like those of last summer, the maintenance of army organization and system is unquestionably essential; the greater the emergency and the difficulties, the more important this becomes. By working in this way all possible conflict with personalities or with regulations are avoided, and the danger of preference is not to be feared. Aid offered in this way was always willingly accepted and appreciated, and gave the assurance of reaching where it was most needed, rather than to the most apparent distress, which too often would be the nearest at hand.

An official in charge knowing the conditions and the needs of the whole has the best opportunity of pointing out the place of greatest demand. A commissary who is daily searching for the required stores for the camp knows better than any one the kind of foods most needed and where; and the surgeon knows the requirements of his hospital outfit, whether medicine or foods or special hospital supplies. In this distribution of supplies, when from the distance from home and the hurry of departure, economy is most essential, this care in distribution becomes most important to a successful undertaking.

Viewed from the experience of last summer, in order that this work should be carried on successfully, it is necessary that:

(*a*) It should be directed toward supplying such needs as have resulted from the confusion and hurry in the initiating of a large campaign.

(*b*) It must be carried on with deference to the

judgment of the regular officers in the command, and should be particularly directed to supply the needs which have been found lacking, and which they better than any others are in a position to appreciate.

(*e*) The work must be accomplished without call on the regular service for aid, either in transportation or distribution; that is, it must be a stream of supply from an independent source, and one whose presence is felt only by the relief it brings.

Clinical Department.

THE REPORT OF A CASE OF PUERPERAL ECLAMPSIA WITH COMPLICATIONS.

BY EDMUND E. HILL, M.D., SUNCOOK, N.H.

I PRESENT for your consideration the report of a case which occurred in my practice about a year ago, and which I deem interesting and worthy of note, not so much for the case *per se* as for the complication which arose during patient's illness. The history is as follows:

Mrs. K., age twenty-seven, American, of medium height and well nourished, called at my office April 2, 1898, and engaged me to attend her during confinement, which, she said would be about the first of June; she was then seven months pregnant. She has during this time suffered no inconvenience whatever, except some slight nausea and vomiting the second and third months.

For a week previous to consulting me she had had slight pains in the lumbar region, and for this reason, together with increased frequency in micturition, she thought she must have some kidney trouble. I make it a rule, if possible, to examine the urine of every pregnant woman engaging my services at some time during the latter months of pregnancy. I did so in this case not only for my own satisfaction but for the soothing influence it might exert upon the nervous system. Result of analysis negative, or, in other words, normal. I did not think it necessary to examine it microscopically. A few days later I made known to her the result of the analysis and noted its pleasing effect.

I heard nothing more from her until Sunday afternoon, May 1st, just about four weeks from the time of her former visit. She was now eight months along, complained of a severe headache located near base of brain with darting pains in neck; five days before had had a similar headache lasting two or three hours; had not felt quite as well since first attack. Prescribed Antikamnia in five-grain doses and a solution of bromide of potassium to be taken at bedtime. Was aroused from slumber the next morning at 2.45 by Mr. K., husband of my patient, who stated that he had been awakened from sleep about one o'clock to find his wife sitting up in bed grasping her head with both hands and complaining bitterly of a severe pain in the back of her neck. In a few seconds she threw up her hands and fell back in a spasm; he wished I would go and see her as soon as possible. I went with fear and trembling. Upon my arrival found she had had in all three convulsions, each lasting for a few seconds; had not had any during last half hour; was feeling quite well but very excitable. No dilation of os uteri found upon examination gave 30 grains each of bromide of potassium and chloral hydrate per rectum, which produced a quiet sleep; left a solution of the six bromides, one teaspoonful to be given every two hours, directing them to call me at once should she have another spasm. I left for a few hours. For unavoidable reasons it was 3 P. M. before I saw the case again; had had one more convulsion during my absence, making four in all; was now in a semi-stupor. I informed the husband of the true condition of affairs, and that I desired a consultation. Dr. Walker, of Concord, was summoned by telephone, and in less than an hour was upon the spot. It was decided that patient was suffering from eclampsia, and the first and only thing to do was to empty the uterus as soon as possible. Patient was etherized, manual dilation performed, and a dead child extracted after some difficulty, by version; during the whole time all necessary antiseptic precautions were observed. Called at 9 P. M., patient had recovered from ether fairly well; was quite comfortable. Temperature was 99°, pulse 100, and respiration 18.

May 3d. Rested easy during night; could pass no urine; catheterized and drew away eight ounces. Temperature 101°, pulse 115, respiration 20.

May 4th, third day. Taking nourishment well; lochia normal; temperature 101½°, pulse 115, respiration 20. Ordered magnesium sulphate, one drachm every hour until bowels moved freely, hoping it might also reduce the fever.

May 5th. Bowels moved three times from salts given the preceding day. Temperature 102½°, pulse 120, respiration 24. Ordered a vaginal douche of corrosive sublimate 1-3000 to be given morning and evening.

May 6th, fifth day. Temperature 102½°, pulse 120. Odor from lochia quite disagreeable; complained of pain in the left iliac region, although no localized point of tenderness could be found.

May 7th. Temperature 102¾°, pulse 122; pain over region of bladder; urine loaded with albumen; pain on left side more severe; lochia very offensive. Introduced a Sim's speculum into vagina and scraped out uterus with a dull curette, following this with a uterine douche (corrosive sublimate 1-5000).

May 8th. Is resting fairly well nights; urine high colored and concentrated. Left a solution of sweet spirits of nitre and citrate of potassium.

May 9th. Temperature 102°, pulse 120. Gave another uterine douche; seems a little weak this morning. Ordered a teaspoonful of brandy in milk every two hours. Left calomel, five grains, and bicarbonate of soda, twenty grains, to be followed in a few hours by a rectal enema.

May 10th. Summoned this morning by telephone; patient had had a secondary hemorrhage, lost considerable blood and was quite pallid when I arrived. Complained of not being able to see very well. Temperature 102°, pulse 124. Ordered brandy every hour in drachm doses, small doses of ergot, and enough morphia to ensure rest; pain in side not as severe.

May 11th. For the first time since May 1st had a natural movement of the bowels; troubled a good deal by gas; tongue moist. Temperature 103½°, pulse 132. Ordered tincture of mux vomica, five drops every three hours; nourishment every two hours.

May 12th. Temperature 100¾°, pulse 100. Tongue moist; gas less troublesome; bowels not as distended; vaginal douche every six hours. Discharge from uterus more abundant when lying on right side.

May 13th. Temperature 100°, pulse 108; restless; complains of shooting pains in right lumbar region and both sides of chest. Codeine, one-quarter grain every three hours, kept patient easy.

May 14th. Temperature 99°, pulse 108; complains of pain in left groin. Left thigh and leg swollen, pearly-white and extremely tender; wrapped the limb in cotton batting and covered with oiled silk.

May 21st. Just one week from last report. During this time there has been very little change of temperature. Tongue dry and hard; neuralgia troublesome; swelling in limb has diminished. Discharge from uterus very abundant. Examination by vagina revealed nothing of importance. Examination of abdomen. From a point corresponding to the left ovary and extending upward into the left lumbar region and to within about two inches of the median line could be felt the elongated outline of a tumor-like mass about the size of a large cocoanut. On palpation a gurgling sound could be heard followed immediately by a profuse discharge from the vagina, and patient would complain of feeling faint.

May 22d. Temperature 102°, pulse 120. For the first time in three weeks passed a very little urine without the use of catheter. Have washed out bladder with plain water every morning and night for a week.

May 24th. Nurse informed me patient had had a bad spell at 5 A.M.; came near fainting while being douched; recovered under two drachms of brandy. Ordered ten minims of digitalis every four hours. Temperature 102°, pulse 120.

May 26th. Swelling in left leg very nearly gone; discharge from uterus profuse as ever, and very offensive; taking nourishment well, consisting of egg-nog, milk and brandy, malted milk, Mellin's food, etc. Sat up ten minutes to-day.

May 28th. Temperature 99°, pulse 120. Complains of a good deal of pain in left side of abdomen; is getting deaf; complains of ringing and buzzing in ears, particularly the right.

June 1st. Is taking nourishment well but is daily growing thinner; sits up five or ten minutes a day; restlessness is controlled in a measure by quarter-grain doses of codeine given every three hours.

From June 1st until June 12th, (time of patient's death) the temperature ranged from 99° to 102°, pulse 108 to 128, respiration from 30 to 40. In the meantime Dr. Walker was consulted as to the advisability of operating upon this abscess, but, as it was discharging freely of itself, it was not thought best. Patient continued to grow weaker day by day and finally succumbed June 12th.

With your permission we will take a brief *résumé* of the case: As near as I can learn from those who were intimately acquainted with our patient, she had suffered from more or less pain in her left groin during the entire period embraced in the eleven months of her married life. From an authentic source we also learn that a few months before marriage husband had contracted gonorrhea, and during winter and spring preceding birth of child had been a great sufferer from articular rheumatism so called, presumably gonorrheal arthritis. At the beginning of the ninth month of gestation was seized with puerperal eclampsia, after delivery. She developed a cystitis which refused to yield to either local or general treatment, and the use of the catheter could not be dispensed with during the entire six weeks of sickness. Had a secondary hemorrhage on the tenth day, which weakened patient much. First complained of pain in left groin, which afterwards extended up into left lumbar region about the sixth day, the discharge began at this time; this pyosalpinx or pyoöphron will be referred to later on. The neuralgic pains were first noticed on the thirteenth day and continued first in one place, then in another, until the end. Phlegmasia alba dolens was first noticed the fourteenth day, beginning in the left thigh and working downward. I look upon this as a secondary phlegmasia due to septic absorption.

During illness temperature ranged between 99° and 103°, pulse between 108 and 132, respiration between 20 and 40. I have noticed that when the pulse remains above 100 for any length of time in an obstetrical case, trouble may be looked for before the case is discharged.

Treatment. — Although all antiseptic precautions were taken in regard to catheter and soft parts, yet a cystitis developed about the ninth day. Washed out bladder in morning with plain water and at night used a saturated solution of borax, and opium in suppository form for relief of pain, gave internally diuretics and demulcent drinks, such as elixir buchu and acetate of potassium, twenty-grain doses of acetate of potash in half a tumbler of water, lithia and apollinaris water, for gas in stomach and bowels, five drops of tincture nux vomica every three hours, as a tonic, tincture chloride of iron, ten drops every four hours; for the heart, tincture digitalis and cactina pellets.

Nourishment. — Egg-nog, malted milk, Mellin's food, beef tea and plain milk, nourishment to be taken every two hours during day and every three hours during night, with very few exceptions; amount taken each time, one cupful; brandy, whiskey and wine administered the last three weeks.

In conclusion, I will say that in my opinion this pyosalpinx did not originate at time of patient's illness but rather nine or ten months before. You will recall to mind my previous statement that she had suffered from more or less pain in the left ovarian region since marriage, and that at or about this time her husband was reported as having gonorrhea. Might it not be possible that the gonococci entered the uterus at this time, found lodgment in the Fallopian tube, kindling a smouldering fire from which originated a chronic salpingitis, accounting for the pain, and which was finally fanned into a blaze which swept everything before it. The result of this salpingitis closely resembles in its effect the destruction which follows a stroke of lightning, differing only in its mode of onset. We have all watched a thunder-shower during the summer months, have seen the flash of lightning and immediately after heard the thunder-clap; in this case the flash was preceded and not followed by the clap.

The oft repeated question, "Is marriage a failure," can, I think, in this case be answered in the affirmative.

A New Association. — We learn from the *Journal of the American Medical Association* that an association for the promotion of public hygiene has been organized in Germany by V. Leyden, Rübner and other prominent members of the profession, and officials. Lectures, meetings, circulars, everything tending to educate the people in matters of hygiene is included in its scope.

Medical Progress.

REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D.

(Concluded from No. 7, p. 166.)

Marandon de Montyel [10] has studied the condition of the knee-jerk in the three periods of general paralysis in the same patients and has come to the following conclusions: In general paralysis the knee-jerk is much more frequently abnormal than normal; it is much more frequently exaggerated than diminished, and moderate exaggerations are more frequent than marked. It is more frequently altered in the first than the second and in the second than in the third period. It is most often exaggerated in the depressive form of general paralysis. Frequency of exaggeration of the knee-jerk is in inverse ratio to the frequency of troubles of speech. The exaggeration is not due to the suppression of cerebral influences, since it has its minimum frequency in the last period, where the suppression is, on the contrary, at its maximum. The degree or form of the alterations of the knee-jerk has no prognostic value. It is not correct to say that the preservation of the knee-jerk is associated with a minimum of physical signs, since this preservation is more frequent in the third period than in the other two. It is not uncommon that, in remissions, the alterations of the knee-jerk persist when the physical signs have so far improved as to pass unperceived. This is an important element to investigate in determining whether the cure is only apparent. In alcoholic patients as compared with syphilitic the knee-jerk is more often altered, either exaggerated or diminished. It is impossible to establish any relation between the alterations of the knee-jerk and the disturbances of sensibility to pain or touch.

The same writer [11] has also studied the condition of the tactile sensibility in the same patients in different periods of general paralysis, and has come to the following conclusions: In 70 per cent. of the investigations he succeeded in confirming the condition of the sensibility, the failures being more numerous in the more advanced stages of the disease. In 12 per cent. of the cases he found the tactile sense altered, exaggerated, diminished, lost or delayed, but in uncomplicated cases there was no form of paresthesia. The changes were always general and never localized. The rarest change was exaggeration, the commonest, diminution. The sensibility seemed to be more involved with the greater progress of the disease but the tactile sensibility was always found normal in remissions. It was more affected in states of agitation than in calm states and it was always normal in depressive forms with hypochondriacal ideas. The exaggeration or loss of sensibility was never observed in periods of calm, but diminution was observed in any state of the disease. The disturbances of touch are commonest in the expansive form and least common in the demented form. It was impossible to note any relation between the condition of touch and the habit, which many paralytics have, of pulling off the clothing. The alterations in the sense of touch in the first two periods of the disease were most often seen in patients with more marked motor troubles. Disturbances of touch have been found only in connection with alcoholism and syphilis, and were more frequent in alcoholic subjects than in syphilitic. A transitory anesthesia, preceding motor troubles, is the only alteration of sensibility of aid in the early diagnosis of general paralysis. Disturbances of touch seem to indicate, in the first period, that the progress of the disease will be neither hyperacute nor very long.

[11] Arch. de Neurol., Nov., 1898., March, 1899.

CONGENITAL PREDISPOSITION IN SEXUAL PERVERSIONS.

Féré [12] insists upon the importance of a congenital predisposition in the causation of perversions, and while he admits that accidental circumstances play an important rôle in the determination of the character that the perversion assumes, he believes that usually, when an accidental exciting cause alone seems to have given rise to the condition, there is probably a congenital predisposition. He states that every one is subjected repeatedly to the same causes that give rise to perversions in some individuals, or to precisely similar and quite as active causes, but that perversions arise only in those who are predisposed, and in whom the causes, therefore, become active. Féré reports a number of cases of perversion in which he was able to trace a distinct abnormal tendency in early infancy and childhood, even before actual perversions were manifest; and although the perversion seemed to follow a cause that was purely accidental and acquired, nevertheless, the history of these cases shows that the cause acted upon abnormally receptive individuals. As to the treatment of this condition, he says that anything that tends to cure it is allowable, whatever it may be; but that heterosexuality is abnormal in these individuals and not physiologic, and that the substitution of heterosexuality for homosexuality does not fulfil a physiologic function. He closes by saying that the ideal to be achieved in these anomalies is not to give pleasure from normal functions, but to lead the subjects to become continent.

MORAL INSANITY.

Müller,[13] after a very thorough review of the literature, attempts to give a clinical description of moral insanity. It is probably a congenital mental disturbance, the characteristic of which is the absence or diminution of the intellectual feelings and aims. In some cases the intellect is disturbed, and the patient is more or less of an imbecile; in others this does not appear to be the case, the patients having a high intellectual development. The symptoms appear in childhood, and are characterized by a peculiar lack of affection and obedience, a tendency to cruelty, a failure to perceive those elements of life which are commonly regarded as noble or beautiful. The patients have neither conscience in their conduct nor repentance for their misdeeds. They are egotistic, selfish and irritable. They often show in early life various forms of perversion, which do not disappear, but rather become more complex with growth. Often these patients have most fantastic ideas or fail to perceive error in their normal relations. Sometimes they are extremely credulous, nearly always showing marked tendency to mendacity and swindling. A curious feature is the skill with which they frequently defend or excuse their misdeeds. Left to themselves, they usually lead the life of vagabonds or tramps. Their crimes are often apparently

[12] Revue de Médecine, Nov., 1898.
[13] Archiv für Psychiat., xxxi, 325.

aimless; they steal not so much for the object stolen as for the perpetration of the act. Stigmata of degeneration are frequently present. The cause is generally supposed to be a tendency inherited from parents of neuropathic characteristics. It is possible, however, that diseases of the brain occurring in early childhood may be responsible for some instances. The diagnosis is to be made (1) by the fact that the changes are present in early youth; (2) the existence of a neuropathic ancestral condition; (3) the presence of certain characteristics that belong to the so-called hereditary degenerative insanities; (4) the existence of psychic or nervous anomalies; (5) the existence of certain deviations from the normal structure of the body; and (6) intellectual abnormalities. Physiologically, Müller concludes, with an approval of Berze's belief, that the condition is due either to an abnormally facile movement of the associations that interferes with the fixation of perceptions and ideas and is associated with imbecility, or an early development of the critical faculty that leads its possessors to deny authority, and, thereby, to lose the feeling of gratitude, filial affection, etc. The prognosis is usually unfavorable. The treatment consists essentially in the removal of such cases to suitable institutions, where they may be watched, and, as far as possible, improved by education. It must be remembered that when, under such circumstances, the patient apparently improves in character restoration to society is almost invariably followed by a relapse. The prophylaxis must begin with the parents. In general it may be said that if these are alcoholic, there is greater reason to expect moral insanity in the offspring.

THE MEDICO-LEGAL ASPECTS OF HYPNOTISM.

It is generally conceded that hypnotism is a pathological and not a physiological condition. When resorted to too frequently it is liable to bring on mental deterioration. It may lead to chronic headache and hysteria; it may induce an outbreak of insanity; in a few cases it has been directly or indirectly responsible for the death of the patient. The question whether the physician is justified in using a remedy that presents so many dangers to life in cases of diseases that are so little dangerous as are hysteria and neurasthenia, Kuh[14] answers emphatically in the negative. His experience has been that suggestion in the waking state is almost equally efficient. Hypnotism should be used as a therapeutic agent only when other methods of treatment and suggestion have failed. The question, Can the hypnotized fall victim to crime? has been answered affirmatively by those whose experiments were made in the laboratory, but forensically cases confirming this assertion are exceedingly rare. That the hypnotized can be used as a tool in the service of crime has been positively stated by those who have made experiments in the laboratory. From practical life, however, Kuh could find only one case in substantiation. The reasons why hypnotism is so rarely used for criminal purposes are that: (1) Not every person can be hypnotized even when willing; (2) not all suggestions are acceptable to the hypnotized, and those that are particularly distasteful to him or foreign to his habits and character are often rejected. Thus, Richet has published the following rather amusing example: One of his subjects, who allowed himself to be metamorphosed without difficulty into an officer, a sailor, etc., refused on the contrary, with tears in his eyes, to be changed into a priest, a refusal that the character and habits of the subject and the environment in which he had lived sufficiently explained. (3) There is in the majority of cases no blind, absolute obedience. The hypnotized may awake at any moment during the proceedings, and this is particularly liable to occur when his suspicions are aroused by anything that is going on around him, or if an inconvenient suggestion be given just before the time arrives at which the suggestion is to be executed; (4) complete loss of memory for what has been going on during hypnosis is not by any means a rule lacking exceptions; (5) finally, if all of these difficulties have been overcome, the way in which the criminal act would be executed would immediately suggest the existence of hypnotic influence. It would be an automaton that commits the crime, unconscious of antecedent and surrounding circumstances, and uninfluenced by the presence of witnesses or by any unforeseen event. The tool being supposedly devoid of all reasoning power in this state, it would be necessary to give such suggestions as would cover all possible contingencies that might arise during the commission of the crime; otherwise the deed would necessarily be done in a clumsy and impulsive manner. These are the principal reasons why hypnotism is so rarely used by the criminal classes. As to the responsibility of the hypnotized, if the possibility that the person was caused to commit the crime by hypnotism is acknowledged, then such a person must be considered irresponsible for his action, for hypnotism is a pathologic state in which the will-power of the subject is affected to a greater or less extent.

FAMILY CARE OF THE INSANE IN RUSSIA.

Sparsky[15] has made an inquiry into the condition of the insane boarded out into the care of peasants in certain villages of Russia. The number thus boarded out has been 363 in three years, and at the end of that time 255 remained in the villages. The reasons for the return of a certain number of the patients to the asylum are very numerous. The commonest is a period of excitement, during which time it is impossible for peasants in poor circumstances to care for the patients in winter, where they have sometimes only a single habitable room. It is wholly exceptionable to send them back because of ill-treatment while under the care of the peasants or for abuse of alcohol. The diet was almost wholly vegetable, meat being served only once or twice during a fortnight, yet three-fourths of the patients were in an excellent state of nutrition and most of the rest were old persons. Two-fifths of the patients presented cases of terminal dementia; epilepsy, idiocy and other forms of dementia coming next in frequency. Most of the patients worked, aiding the peasants in the fields; they worked without being forced to do so, and their labor is so satisfactory to them that they do not desire to return to the asylum. Many patients are attached to their hosts, and *vice versa*. The patients are closely watched by a supervisor, who lives in the village; the physician comes once a week, the asylum being seven kilometres from one village and three from another. The sexual conditions are carefully watched. In three years there has been only one case of pregnancy in a patient and one attempt at rape on the part of a patient.

[15] Questions de Neurol. et de Psych. Med., vol. ii, p. 513, 1897.

THE ROLE OF AID SOCIETIES FOR THE INSANE.

Morel,[18] after commenting on the increasing and rapid development of public opinion regarding this question, and on the consequent activity of organized work in connection with it, divides his subject into the following heads: (1) What can be done for the lunatic *before* his removal to an institution? (2) *during* his period of seclusion? (3) the assistance of the family deprived of his support; (4) what ought to be done for a patient so far recovered that seclusion in an asylum is no longer necessary? (5) the development of public assistance; (6) the special education of children who have inherited tendencies to mental disease; (7) provision of special asylums for children of defective development and idiots; and (8) means of diminishing the causes which might predispose to insanity.

Dr. Morel considers that it is the duty of all charitable organizations to extend their patronage to the insane and their families; that suitable members should be set apart for visiting reported cases, and as far as possible for treating those for whom enforced seclusion is deemed unnecessary. In the case where seclusion is absolutely inevitable, the patient ought to be guided and watched over to the very doors of the asylum, and his family protected, helped, and, if need be, supported during the period of absence of the bread-winner out of the funds of the society or societies undertaking such work. Thus, keeping each patient well in sight during his seclusion, the society must be ready to take him by the hand immediately on his release, whether entirely or partially recovered, and to continue its good offices until he is once more able to resume his place as bread-winner and responsible member of the social community.

As necessary side issues of the main question, Dr. Morel advocates the establishment of special asylums for the development and education of those innocent victims of parental weaknesses who are yet capable of moral and mental training, and for the protection and care of such as are too hopelessly sunk in imbecility to need other than the usual bodily attention which their condition demands.

In conclusion, Dr. Morel sketches out a plan for the formation, organization and administration of a society having for chief object the duties marked out above, impressing on his readers the growing necessity for such societies in view of the steadily increasing attention given throughout all the countries of Europe to mental disease and its victims.

Reports of Societies.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held at the Academy of Medicine, in New York City, May 9, 10 and 11, 1899.

FIRST DAY.

The opening address was made by the President, Dr. Beverley Robinson, of New York, the title of which was

THE IDEAL PHYSICIAN — HIS CHARACTER AND ATTAINMENTS.

He referred to the noble example of the men whose portraits adorned the hall of the Academy of Medicine, in which the meeting was held. Their lofty character and superior attainments made them the leaders of men and medicine in their day and generation. He inveighed against the spirit of commercialism, and charged much of this to the invasion of specialism, for the general practitioner was and is ever cast in a different mold and has other purposes. Even though only few, comparatively, may have a sordid spirit, it should be discountenanced and banished. He exhorted his hearers to do their utmost, both individually and collectively, to elevate the social and scientific plane of their profession. They must be leaders in reform, not alone in sanitary and hygienic matters, but in everything that concerns the public good, whether in politics, morals or education. Their education must include the heart as well as the mind, and while not intruding on the domain of theology, the physician could and should minister to the soul as well as the body and cultivate sympathy with his patients. He cautioned against the undue influence of supposed scientific advances as against the results of one's own experience, and cautioned the physician not to allow his practical judgment to be overruled. He must direct the specialists' work and carefully provide that no narrow view be taken of the patient's ailments. In this way he will be of the greatest benefit to the patient and advance practical medicine. Laboratory work should be fostered, but the province of the clinician should not be ignored.

Dr. Vincent Y. Bowditch, of Boston, read a paper entitled

THE SUBSEQUENT HISTORIES OF "ARRESTED CASES" OF PHTHISIS TREATED AT THE SHARON SANITARIUM.

Dr. J. Edward Stubbert, of Liberty, N. Y.: I was very much interested in the paper of Dr. Bowditch, bearing, as it does, upon the curability of incipient cases of phthisis, and emphasizing the remarks made by another member of the Association in regard to the importance of nourishment *versus* climatic influence. I think the results obtained by Dr. Bowditch are very encouraging, especially when we bear in mind the fact that the work was carried on in a climate which is not considered particularly salubrious.

The temporary absence of bacilli in the sputum of tuberculous patients is well known. I have in mind at present a patient of Dr. Janeway's who has a large cavity in the upper portion of the left lung and a fibrous condition of the lower portion of the lung, in whose sputum the bacilli were absent for five weeks, although they were frequently searched for by three different examiners. It is not uncommon in my experience in incipient cases to get physical signs without being able to detect the presence of bacilli.

Even in sanitariums, special attention must be given to the complications of pulmonary tuberculosis: otherwise, such complications will handicap the patient and interfere with his recovery, even in the best of climates.

Dr. Newton: About half a year ago, my friend Dr. Stubbert sent a girl from the Loomis Sanitarium to her home at Montclair to die. She was suffering from advanced pulmonary tuberculosis. Since her return home, in spite of the fact that she has been living in very unhygienic surroundings in a tenement house, she has gained twelve pounds in weight and apparently is going to get well in spite of us.

[18] Pamphlet entitled, Quel doit être le Rôle du Patronage à l'égard des Aliénés? by Dr. Jules Morel.

DR. FRANCIS H. WILLIAMS, of Boston: I would like to ask Dr. Bowditch what his experience has been with the treatment of cases of pulmonary tuberculosis in the wards of a general hospital, during the limited time they are kept there, compared with the sanitarium cases. I have often been gratified to see such patients improve in a general hospital in a remarkable manner simply on the food and care such a hospital affords.

DR. BOWDITCH: Poorly nourished patients suffering from pulmonary tuberculosis who are admitted to a general hospital often improve temporarily, which is doubtless due to the better food and care they receive, but they cannot get the treatment there that they receive in a special hospital. They cannot get the same amount of fresh air that they would in a properly regulated sanitarium. If we could treat this class of patients by themselves in hospitals especially constructed for their use, we could do more for them even in the city.

DR. EDWARD R. BALDWIN, of Saranac Lake: I would like to say that the authorities at the Adirondack Sanitarium are in constant correspondence with 115 patients who have been discharged during the past ten years. Most of these are in fairly good health. Some have relapsed slightly, but the majority are able to reside at their old homes and resume their usual occupations.

DR. STUBBERT: I would like to ask what distinction Dr. Bowditch makes between arrested cases and apparently cured cases.

DR. BOWDITCH: I simply adopted the term "arrested" because I regarded it as a more appropriate term to apply to these cases than "cured," unless a long period has elapsed without a return of the symptoms. I apply it to every case where definite tuberculous symptoms have existed when cough, expectoration and fever have ceased and the general condition signifies a return to normal conditions, even though abnormal physical signs may persist indefinitely.

DR. FRANCIS H. WILLIAMS, of Boston, read a paper on

RÖNTGEN RAY EXAMINATIONS IN INCIPIENT PULMONARY TUBERCULOSIS.

He had examined about 165 cases of pulmonary tuberculosis with the x-rays. His static machine had four revolving plates, six feet in diameter, and four fixed plates, six feet, four inches in diameter. The author considered (1) cases with slight physical signs, but no râles; (2) those without physical signs, that is, whose lungs had been found normal by auscultation and percussion. It was shown in the second group of cases, five examinations with histories having been cited, that the x-ray examination gave warning of tuberculosis before any departure from the normal was obtained by auscultation and percussion. One reason for this is that if the density is much below the surface of the lung as in central pneumonia, its presence is not recognized by auscultation and percussion, but a shadow of the consolidated portion of the lung is cast on the fluorescent screen. The shadow is also cast by a slighter degree of congestion than can be revealed by auscultation and percussion. Dr. Williams has proven experimentally by shadow tests that a lung in pneumonia or tuberculosis if sufficiently diseased will offer ten times or more resistance to the x-rays than the healthy lung.

The x-ray examination enables the physician also to recognize some old or latent areas of tuberculosis which might otherwise be overlooked. Tuberculosis may be associated with bronchitis or emphysema and thus be more quickly recognized. Dr. Williams had had eight cases of the former and nine of the latter combination in which the diagnosis was corroborated by the discovery of tubercle bacilli.

Dr. Williams rightly claimed that we have in the fluorescent screen a more ready, convenient and delicate method of recognizing an abnormal condition of the lung than we have in x-ray photographs, and the screen has the advantage of revealing the mobility of the diaphragm and the heart.

DR. KNIGHT: I have had the opportunity of examining quite a number of Dr. Williams's cases, and in many of them, although I could find no physical signs by auscultation or percussion, the rays revealed signs of incipient tuberculosis. The fact should be borne in mind that physical signs of consolidation should not be looked for at a very early stage of the disease. I see patients for months in whom I can find distinct localized catarrhal signs without any signs of consolidation or any change in the percussion note. I hope that men who have had practical experience with the Röntgen rays in this connection will continue the discussion.

DR. STUBBERT: I was interested in listening to Dr. Williams's paper and comparing his remarks with those made last year. This comparison shows conclusively that satisfactory progress is being made from month to month in this field of research, and it is apparent that nothing in the treatment or diagnosis of pulmonary tuberculosis has made such great strides recently as the use of the x-rays, especially in diagnosing incipient cases. Another point of interest is the relative value of the fluoroscope and the fluorescent screen. Last year I stated that I had abandoned almost entirely the use of the former for the latter; since then I have not used the fluoroscope in more than three or four cases, as a screen gives a much better picture.

Dr. Williams's remarks have strengthened me in my belief that radiographs are not satisfactory. I have never been able to successfully photograph an incipient infiltration in the lung, and others have had the same experience.

I am fully in accord with the statement which has been made that the use of the x-rays should be invoked in every doubtful case of pulmonary tuberculosis. As Dr. Otis has said, we cannot depend absolutely upon tuberculin. The peculiarities of the patient may mask the diagnosis. I have yet to see an incipient case that could not be accurately diagnosed by means of x-rays. We may sometimes be misled by a slight thickening of the pleura at the apex, but this occurs very rarely, and such a condition probably cannot exist without some slight underlying morbid process of the lung. The x-rays are also valuable in cases where there are scattered foci throughout the lung, which on account of their smallness do not yield physical signs. These cases can be very accurately diagnosed and the area definitely mapped out by means of the fluorescent screen.

I was also interested in what has been said regarding the use of the x-rays in emphysema and bronchitis. In the former, very definite physical signs have been obtained, but in bronchitis we have not been able to do anything with them.

DR. LANGMAID: I am astonished at the limitation

of the movement of the diaphragm with such slight abnormal conditions of the lung. I never suspected it before.

Dr. Williams: In nearly, if not quite, all of the cases to which I referred in my paper there were no râles. As regards the value of x-ray photographs in comparison with the fluorescent screen, thus far, in my experience, the latter will detect many abnormal conditions earlier and better than the former. I also regard the fluorescent screen as superior to the fluoroscope.

Dr. S. G. Bonney, of Denver, read a paper entitled

SUGGESTIONS CONCERNING EARLY DIAGNOSIS IN PULMONARY TUBERCULOSIS.

He analyzed his recorded cases, numbering 546, seen in private practice and continued under observation for a considerable period in Colorado, although contracted elsewhere. Seventy-one per cent. of these arrived in that State with distinct evidences of tubercular infection in each lung; 19.2 per cent. had well defined cavities. The average time of delay in the cases was a little over eighteen months; 20.2 per cent. presented the history of a sudden hemorrhage as the first symptom distinctly referable to the disease.

The thorough and painstaking examination of the chest immediately upon the development of suspicious symptoms, and its frequent repetition if necessary, will usually suffice through the detailed application of the principles of auscultation and percussion, in establishing for clinical purposes a sufficiently early diagnosis. As a matter of fact, such an examination is seldom made until a provisional diagnosis has become apparent from the rational symptoms, and the consultant at once recognizes physical evidences of advanced infection. Is it not, then, of practical importance, prefatory to a consideration of the more recent aids to the recognition of consumption, to continue to emphasize a more strict and conscientious adherence to the principles of physical diagnosis now admittedly ignored in so many instances? Apropos of this I would especially condemn:

(1) Delay in instituting any physical examination whatever until long after the development of pronounced constitutional and pulmonary impairment.

(2) Failure to examine on the bare skin, the presence of clothing effectually preventing any approach to accurate results.

(3) Neglect to examine the entire chest, the bases, interscapular spaces, and axillary regions being frequently overlooked.

I would deplore particularly the existence of:

(1) Erroneous conceptions concerning the significance of the absence of percussion-dulness at the apices, an active process often being capable of recognition by ausculation considerably before the evidences of consolidation are apparent.

(2) The non-recognition, in the absence of râles, of the various modifications in disease of the normal respiratory sounds.

(3) Inaccurate interpretation of localized diminished intensity of auscultatory sounds, elevation of pitch, harshness of quality, and prolongation of expiration.

I would severely criticise:

(1) Failure to utilize cough preceding forced inspiration in eliciting the presence of slight moisture in the finer tubes.

(2) The non-appreciation of the almost pathognomonic significance of a circumscribed bronchiolitis, even in the absence of dulness or other auscultatory signs.

Dr. Frederick I. Knight, of Boston: I wish to repeat here the statement which I made in my remarks on this subject last year, namely, that the early diagnosis of pulmonary tuberculosis should not be made for the sake of sending your patient to Colorado or anywhere else, but that it should be made in order that the proper treatment may be instituted at once.

In regard to the presence of bacilli in the sputum in the earlier stages of the disease, I must say that my experience rather differs from that of Dr. Bonney. I have very rarely failed to find the bacilli in the sputum of patients who present themselves to me, and I see many cases early in the course of the disease. It is true that they are patients with cough, and usually with a little expectoration. The tubercular disease that develops without cough naturally falls into the hands of the general practitioner.

According to Dr. Bonney's statistics, the hemorrhagic cases are the ones which delay longest before going to Colorado. This is interesting, and is in line with the pretty generally admitted fact that those cases pursue a longer and usually a more favorable course than the other types of the disease. They for a long time may complain of very little cough or expectoration, and the disturbances of their general condition is not severe enough, in their opinion, to oblige them to consult a physician or adopt any radical measures of treatment.

Dr. John O. Roe, of Rochester: There is one diagnostic feature in connection with this subject which I consider one of the most important and which has been overlooked. I refer to a laryngoscopic examination, which I think should be made in every case of suspected incipient pulmonary tuberculosis. I quite agree with Dr. Knight that the bacilli may usually be found at a very early stage of the disease; in fact long before you can detect any marked physical signs, and even prior to this the laryngoscope will reveal a condition of the larynx which, to the skilled laryngologist, will indicate the presence of incipient pulmonary tuberculosis. The changes in the larynx are characterized by an anemic condition of the mucous membrane, due to interference with the circulation of the parts, and indicating pulmonary involvement.

Dr. R. H. Babcock, of Chicago: Dr. Bonney's paper was so complete that it would seem as if there was hardly room for anything more than favorable comment upon it. Nevertheless, I should like to speak of what struck me particularly, and that is the very large percentage of his cases, namely, 71 per cent., who had been kept at home for varying periods before they were sent away for climatic treatment. The doctor's conclusions were that these cases remained at home chiefly or largely because of delayed diagnosis. That unquestionably is a correct conclusion in many of them, but is it a legitimate one in regard to all of them? Is it not true that a very large number of patients are kept at home in the care of the family physician for some ulterior motive than the patient's good? Is it not true that many are kept at home because the family practitioner does not wish to lose sight of the case? This perhaps is a very pessimistic view of the matter, and attributes to the rank

and file of the profession methods which are unworthy, and perhaps I should apologize to the profession for even insinuating so much, but I believe it is impossible for the rank and file of the profession, no matter how ignorant they are about physical diagnosis, to keep those patients under their care for eighteen months without recognizing their true condition.

Another motive, which is not an unworthy one, is the belief on the part of the attending physician that his patient will improve at home under proper treatment, and that it is unnecessary to send him away. If that is the reason for the delay, then the 388 cases mentioned by Dr. Bonney furnish a striking commentary on the incorrectness of such an opinion. For my part, I insist upon the importance of an early diagnosis for the very purpose of sending the patient away to Colorado. I believe so sincerely that a change of climate will restore such patients in the incipiency of the disease that as soon as I recognize a case in its beginning, I promptly advise such patients to go away. If that advice cannot be followed, then some other advice is given.

In the early diagnosis of pulmonary tuberculosis, I should like to dwell on the importance of temperature. A study of the temperature should never be neglected. We all see cases where the early diagnosis of the disease is difficult on account of the vagueness of the physical signs. There may not be a rise of temperature in all cases, but there is so apt to be a slight rise, perhaps only of one degree, that if the temperature is studied carefully for a week or more, the physician can usually come to a correct conclusion.

I am not a laryngologist, but I must say that I am sceptical about the statement just made that a careful laryngoscopic examination will anticipate a diagnosis of pulmonary disease before it can be detected in the lungs. I have friends at home whom I know are skilful laryngologists, and I have so often called on them to help me out that I cannot believe their failure to recognize a change in the larynx was due to ignorance, but rather that such changes were not there. I have sent patients with incipient disease of one or both apices to laryngologists, and the statement came back that the larynx was practically healthy.

In regard to the significance of hemoptyses, I should like to say that I believe they are nearly always the precursors of pulmonary disease or due to it.

DR. R. G. CURTIN, of Philadelphia: — I believe that ofttimes the main reason why patients are not sent away from home is that they are not ready to go. They may not at first have the means to go away; later on, when the symptoms become more aggravated, the necessary funds may be supplied by their relatives or friends. Other patients are not disposed to leave home, or are afraid of getting homesick. Often it requires six months or a year before such a patient can make up his mind to leave his home.

DR. RICHARD C. NEWTON, of Montclair: — In confirmation of what Dr. Babcock has just said about laryngeal phthisis, I believe the fact is generally admitted — for which we should thank heaven — that it is a comparatively rare, although a distressing, intractable and, in fact, a well-nigh hopeless phase of consumption.

DR. ROE: — The examiner must make the distinction between a tuberculous laryngitis and the laryngitis of tuberculosis.

DR. E. FLETCHER INGALS, of Chicago: — I agree with the statement made by Dr. Roe that even in the very early stages of pulmonary tuberculosis the larynx often presents an appearance which the man who frequently examines that organ will recognize as tubercular. There is a pallor or an atrophic condition of the larynx which leads him to believe that the patient is tuberculous.

I think that the plan of telling your patient to go away as soon as you find out that he has tuberculosis is a mistake. The first thing is to find out is he can go away; if he has money or if his friends can send him. It is cruel to tell him that he must go away before you know that he is able to do so.

DR. C. F. MCGAHAN, of Aiken, S. C.: — I agree with Dr. Roe that an examination of the larynx if often of great value in the early diagnosis of these cases. It is my custom to examine the larynx in all of my cases, and I have now a patient under observation where the larynx is suggestive of tuberculosis, although I can find nothing in the lungs.

DR. E. O. OTIS, of Boston: — Dr. Bonney, in his paper, emphasized the importance of the inherited susceptibility of the patient in the acquirement of pulmonary tuberculosis. In connection with that, I think the question of exposure to the disease should be carefully investigated in each case. Last year, Dr. Loomis, in a valuable paper before this Association, spoke of two other factors in making an early diagnosis, namely, the vital capacity of the individual, as determined by the spirometer, and the lowered arterial tension. These I believe, will often give us valuable indications in making an early diagnosis.

DR. PHILLIPS: — I would like to inquire whether any of the members have noticed a sub-normal temperature in tuberculous patients? In the incipient stage of the disease it seems to me that is almost of as common occurrence as a slight rise in temperature.

DR. KNIGHT: — There is one point in regard to the larynx which should be brought out. I think all laryngologists agree that in incipient pulmonary tuberculosis the larynx may have a suspicious appearance — not an ulcerated condition, but a certain indefinite appearance which has hitherto been not fully described and which Dr. Roe can perhaps describe to us more in detail.

DR. BABCOCK: — I was only expressing some scepticism concerning the doctor's statement that the appearance of the larnyx sometimes indicated pulmonary tuberculosis before an examination of the lungs would show it. I do not question for a moment that the appearance of the larnyx is significant when pulmonary changes are present, but I was surprised that the larynx should indicate pulmonary tuberculosis at so early a stage that careful examination of the lungs would not reveal the presence of the disease.

DR. ROE: — I did not say it was indicative of pulmonary tuberculosis, or at least, what I meant to say was that it was indicative of approaching trouble in the lungs.

DR. ROBERT H. BABCOCK, of Chicago, read a paper on

HIGH ALTITUDE AND HEART DISEASE WITH REPORT OF CASES.

The author reported nine cases in full. Case I was an instance of mitral stenosis, and Case VII of aortic

constriction. In both an unyielding barrier to the blood-flow existed, and time had to be allowed for the stream to pass the point of obstruction. In stenosis, systole is slow and forcible so long as compensation is adequate. Acceleration of the circulation at high altitudes would quicken cardiac contractions; with the shortening of systole time would not be allowed for complete emptying of the chambers back of the constriction; stasis in the pulmonary vessels would be promoted, with corresponding dyspnea that might readily grow urgent on exercise.

Conclusions.— (1) All forms of cardiac disease do not contraindicate sojourn at a high altitude.

(2) The ill-effects of low atmospheric pressure in some forms of cardiac disease are explicable on the hypothesis of acceleration of venous flow and corresponding quickening of the heart beats.

(3) Consequently those forms with which high altitude is likely to prove incompatible are pronounced aortic or mitral stenosis, and regurgitant disease when complicated by pleural and pericardial adhesions.

(4) On the other hand, patients with uncomplicated regurgitant lesions, or arterio-sclerosis, with or without myocardial changes, may endure low atmospheric pressure without injury.

(To be continued.)

Recent Literature.

The Philosophy of Memory and other Essays. By D. T. Smith, M.D., Lecturer on Medical Jurisprudence in the University of Louisville. Pp. 203. Louisville: Press of John P. Morton & Company. 1899.

This small volume, admirably printed on excellent paper, is a series of essays, only one of which, that on Memory, has any claim to consideration from a medical point of view. The book is merely an expression of the thought and the theories of its author. The Essay on Memory deals with anatomy and psychology, but with neither in a fundamental way. To certain readers, the book will, no doubt, prove suggestive, but it is hardly to be regarded as a significant addition to our knowledge of the subjects of which it treats.

Hay-Fever and its Successful Treatment. By W. C. Hollopeter, A.M., M.D. Second edition, revised and enlarged. Philadelphia: P. Blakiston, Son & Co. 1899.

In this second edition the author has enlarged the special treatment for the various types of cases, and brought the bibliography up to date. The great difference in opinion on the etiology of hay-fever is briefly outlined by well-selected short references. The author's local treatment consists essentially in thorough cleansing of the nares with Dobell's and similar solutions, followed by drying and applications of oily solutions, which when necessary is supplemented by careful general treatment.

Compulsory Vaccination in Japan. — The Japanese government has recently decreed that vaccination and revaccination be compulsory. Children must be vaccinated before the tenth month, and revaccinated at six, and again at twelve years of age.

PROF. ROBERT W. E. BUNSEN.

The death of Professor Bunsen, which occurred August 16th, at Heidelberg, has removed another of the master-minds of Germany. Original scientific investigation has suffered severely in the last few years through the deaths of Pasteur, Helmholz, Du Bois Reymond, and now of Bunsen. Such men cannot be replaced, nor, fortunately for the world, can their work be destroyed.

Although Bunsen was not primarily interested in medicine, yet his special fields of research, physics and, notably, chemistry, are coming into closer and closer relation with medical science. We may, in the near future, surely look to chemistry for some of the most striking advances in medical knowledge. It is of interest also to note that like Helmholz, in the invention of the opthalmoscope, so Bunsen has done an inestimable service to medicine in his work on electricity, the properties of certain metallic compounds, and spectrum analysis. His first chemical work was the discovery of an antidote for arsenic. This he accomplished in his twenty-third year. Born in 1811, he spent about twenty years after receiving his degree in various German universities as tutor and professor, and finally, in 1852, went to Heidelberg, where he remained until his death. While at Heidelberg he had built a chemical laboratory, which became, under his direction, one of the most celebrated schools of chemistry in the world. He was a prolific writer on scientific subjects, chiefly connected with chemistry; particularly original was his work on spectrum analysis, which, though indirectly, is coming to have a closer and closer bearing upon certain branches of medicine, in connection, for example, with microphotography. In the course of his life he invented some of the most valuable adjuncts of a laboratory, the Bunsen burner being still probably the most indispensable in the hands of a chemist. The battery, photometer and pump known by his name are hardly less useful. It is always interesting to observe how, with all the modern tendency toward specialism, there is likewise a

growing appreciation of the interrelation of the great fundamental sciences. As medicine becomes more of a science as a branch of biology we may look for a constantly increasing dependence of the peculiar problems which medicine offers for solution, upon the allied sciences, and, conspicuously, upon chemistry. Men like Bunsen do much to hasten this hoped-for day.

A STATISTICAL STUDY OF THE RELATION BETWEEN WEATHER AND CRIME.

THAT climate has a certain bearing upon the character of individuals and races has long been appreciated. We recognize, for example, as a race characteristic the active, hardy, unemotional attributes of the northern peoples, as contrasted with the easy-going, sentimental traits of those living in countries further south. These bare facts might suggest to the lover of the statistical method a possible prolific field for research in the study of effects of varying climatic conditions on the characters of persons living in the same locality. Such an investigation has been undertaken by Edwin G. Dexter, and the results of his work published in a recent number of *Science*.

Dexter has attempted to ascertain what bearing certain misdemeanors and other data of conduct have in relation to definite weather conditions. To accomplish this end, through the New York Branch of the United States Weather Bureau, 3,650 days were tabulated as to their prevailing characteristics, whether fair, partly cloudy, rainy or clear, and also as regards temperature, humidity and wind. Armed with these data, Dexter has collected for the same period of time, from records available in New York City, upwards of 400,000 facts; misdemeanors, ranging from assault and battery and suicide to errors made by bank clerks and strength tests in Columbia University. Comparing the characters of the day with the nature of the crime or physical state of the individual, conclusions of interest are reached, affording at least the basis for a valuable sociological study. The following are some of the points learned from a reduction of the double set of data to percentages: "Moderately high temperatures were found to be accompanied by excess in all the misdemeanors considered; low temperatures by deficiencies. The temperature group 80–85° showing an excess of 68 per cent. for assault by males and 100 per cent. for those by females. The next higher group, however, shows a drop to 33 per cent. excess for the former, and an efficiency of 33 per cent. for the latter. This sudden falling off for conditions of intense heat is shown for nearly all classes of data, and is undoubtedly due to the fact that under such temperature there is little energy available for offensive conduct. Death, suicide and the recorded errors in banks alone remain excessive under such conditions.

"The study of humidity in its effect upon the data of conduct gave some interesting results, since it demonstrated beyond a doubt that conditions of low humidity are those most productive of misdemeanor. When we consider that the muggy, sticky days on which we feel it our natural prerogative to be 'out of sorts' are of the opposite character this is quite surprising. The deficiency of disorders on such days is, however, undoubtedly due to the fact that although they are emotionally depressing they are also physically weakening, and however 'ugly' a man might feel, if energy were lacking to be offensively active, the police-court is none the wiser, and the fact is lost to our study."

Further study of the statistics shows that misdemeanors are more frequent upon days we are accustomed to consider agreeable. Suicide is found, contrary to the generally accepted idea, to be more frequent upon pleasant days in May and June.

"Perhaps the most interesting general conclusion to be drawn from the study is that during those meteorological states which are physically exhilarating, excesses in deportment, in the ordinarily accepted sense of the word, prevail to an abnormal extent, while death and irregularities in mental processes (errors in banks) are below expectancy. During such weather conditions, without doubt the quality of the emotional state is more positive than under the reverse conditions, but the results seem to show that in the long run an excess of energy is a more dangerous thing, at least from the standpoint of the police-court, than the worst sort of a temper with no energy."

The value of such work as the foregoing is unquestioned; still we cannot but feel that it is a statistical problem of very unusual difficulty, and one requiring more data than here presented to be convincing. For example, the questions of environment and race, together with the whole category of personal characteristics, seem to have been left unregarded, excepting for a general classification into groups. Places where crimes are committed must also be a source of error in such statistics. Weather conditions would hardly have the same effect in the city as in the country, or in a dark tenement as in the open air. Evidently, therefore, there are numerous sources of error, if only the crime and the weather conditions are considered; nevertheless, the general results are of value, and no doubt will prove the starting point for other and more detailed investigations.

RAINSFORD ISLAND.

THE recent fires at Rainsford Island, which the evidence goes to show were of incendiary origin, must force upon us both the dangers and the difficulties in the administration of an institution of that character. It is a reformatory for boys, which means that its inmates are of a class to be regarded with suspicion and watched with care. If they may be reformed, so much the better, but in the meantime they must be regarded as an abnormal class whose best interests demand the closest surveillance. The wholesale destruction of property which was intended and partly accomplished is a danger to which such an institution must always

be exposed, and against which it must be most rigidly guarded. Recent events go to show that some of our boldest and most desperate criminals are boys under twenty; call them pathological, or degenerate, or the victims of circumstances as you will, the fact remains. This attempt at Rainsford Island. if it prove to be a deliberate plan on the part of certain inmates, means that discipline and not sentiment should prevail, and that everything should be done to uphold the present administration of the island in its efforts to establish a firm rule over its troublesome wards. This the city owes to itself and to its appointed guardians of this particular city institution.

MEDICAL NOTES.

CENTENNIAL CELEBRATION AT LEIPSIC. — The surgical clinic at Leipsic will have a centennial celebration in October, when a bust of Professor Thiersch will be unveiled.

PROFESSOR SANARELLI NOT TO VISIT AMERICA. — It has been generally reported that Prof. Sanarelli was about to visit America, for the purpose of continuing his investigations on yellow fever. We learn from the *Medical News* that this rumor has no foundation in fact, and that he has no present intention of visiting America.

YELLOW FEVER AT SANTIAGO AND HAVANA. — It is reported that a case of yellow fever has occurred at Christo, whither headquarters have been removed, in the neighborhood of Santiago and is the first at that place. Of late the quarantine rules have been relaxed, owing to the fact that there have been no new cases in the city, and officers from headquarters have been in the habit of coming to Santiago daily, returning to headquarters at night. There are no cases among the troops at Havana.

AN EXPENSIVE CRIMINAL FAMILY. — We learn from the *Medical News* that Ada Zurke, who was born in Germany in 1740 and died in 1800, was a confirmed drunkard. Prof. Pellmann, of the University of Bonn, discovered and identified 709 of her descendants. Seven of these were convicted of assassination and 76 others of different crimes, while 144 were professional beggars, 61 lived on public charity, and 181 were prostitutes. Altogether, the cost to the German government of watching, pursuing, trying, and boarding the members of this family has been more than a million and a quarter dollars.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 23, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 44, scarlet fever 16, measles 3, typhoid fever 32, small pox 1.

FIRES AT RAINSFORD ISLAND. — Within ten days two fires have occurred at the reformatory for boys on Rainsford Island. Through vigorous efforts on the part of the officers of the island and others, the first was quickly extinguished with slight loss. The second fire, a few days later, originating in the same place, proved more stubborn, and was not brought under control until a large part of one building had been destroyed, entailing a considerable money-loss. The fires are supposed to have been of incendiary origin, started by inmates.

NEW YORK.

PUBLIC FUNDS FOR SUPPORT OF PRIVATE CHARITIES. — In a communication to Controller Coler, expressing approval of the latter's determination to cut down the appropriation of public funds for the support of private charities, the State Charities Aid Association points out that a number of these institutions are almost wholly maintained by the city, and that the appropriations tend to discourage private benevolence. The statement is made that there are now 282 institutions, which receive annually no less than $3,249,623. The Association advises that the custom of appropriating money for such institutions should be entirely abolished, and that all appropriations for charitable purposes should be devoted to the development and support of the municipal charities. Inasmuch, however, as the present system cannot be discontinued at once without causing considerable disturbance and hardship, it is recommended that a gradual reduction in the amounts given to private institutions be carried out, and that this reform be first applied to the per capita payments for inmates, the expense of whose maintenance in all instances, it is declared, is much greater than for the inmates of the city institutions. It is furthermore recommended that the city should in no case make payment to private institutions until after a thorough investigation, and that expenditures for private charities be provided for in the regular budget, and not out of the excise moneys.

A BABY FARM CONDEMNED. — On information furnished by the Society for the Prevention of Cruelty to Children, a woman was, on August 15th, found guilty of maintaining an authorized "baby farm," and sentenced in the Court of Special Sessions to a year's imprisonment. It was shown that three infants had died within a period of three weeks, and Dr Sinclair, of Lexington Avenue, testified that the children in her establishment were in a very bad state of filth and neglect.

A CREMATORY FOR NYACK. — The Nyack rural cemetery, twenty-three acres in extent and situated a mile and a half back of Nyack, on the Hudson, has been purchased by a New York syndicate, which purposes to establish a crematory in which liquefied air is to be utilized to furnish a supply of oxygen much greater than is possible by any process hitherto employed. The furnace used will be an electric one, and it is claimed that by this new process the incineration of a body can be accomplished in a few minutes by the intense heat evolved. One of the principal objections

to cremation, the long time required for the process, will thus be removed.

DEATH WHILE UNDER TREATMENT OF A CHRISTIAN SCIENTIST. — John Allan Campbell, who is represented as having been a Christian Scientist of the highest sphere, died recently, after having been treated until within a few hours of dissolution by members of his sect. When it became evident that death was near a physician was called in, no doubt for the purpose of signing the certificate for the health department, but the physician very properly placed the case in the coroner's hands. The autopsy made by the coroner's physician, Dr. Donlin, showed that the patient was affected with acute pleurisy, with effusion, cerebral congestion and cardiac hypertrophy and dilatation.

A FATAL CASE OF POLIOMYELITIS. — A child four years and nine months old died on August 15th at Poughkeepsie, of infantile paralysis, after a very brief illness. This is the first fatal case that has occurred there, and the attack is said to have been ushered in by convulsions which appeared to be due to a large quantity of watermelon which the child had taken.

Miscellany.

A PROGRESSIVE OPINION.

THE *Medical News* heads the following excerpt from a recent editorial in the *Medical Times*, a homeopathic journal, "A Step in the Right Direction," an opinion which we would most cordially endorse:

"However valid may have been the reason in the early days of the homeopathic school for identifying its institutions with a distinctive sectarian name, it is a matter worthy of the most careful consideration, if, in the present advanced and ever-advancing state of medical thought, when the most accurate scientific tests are being applied honestly and faithfully to every principle in medicine, and to every new thought developed in the wide range of studies connected with our profession, the retention of that name in our colleges and hospitals does not retard their influence and create in the minds of scores of students in after years a feeling of regret that in a profession ever broadening in its scope and becoming more and more a unit in its work, their diploma, in name at least, is a distinct sectarian one, and out of tune with that broader liberty which looks upon the whole world as its own. There is no disputing the fact, for the records are open to all, that every year many, very many physicians on whose diplomas the name eclectic or homeopathic appears seek and obtain from other colleges a non-sectarian degree, in which no pledge is required or implied of adherence to any one dogma, and giving perfect liberty for that freedom of action based upon a careful education and mature thought. At the commencement of the Cleveland College of Physicians and Surgeons last month, no less than fifteen homeopathic physicians secured the diploma of the college after having spent the winter in study."

THE DETERMINATION OF SOUND DIRECTION.

THE function attributed to the semicircular canals in respect of the determination of the direction of sound has been gradually undermined, and is now more or less discredited. The nature of the mechanism by which the source of origin of a given sound is perceived, therefore, still remains to be explained. There is reason to believe that the appreciation of direction is, *mutatis mutandis*, very analogous to the phenomenon of stereoscopic vision, that is to say, it is in virtue of certain subtle modifications of sound as perceived by both ears that we learn to diagnose direction, just as the slightly inaccurate superposition of two visual images gives the sensation of projection. In the course of a long series of observations carried out at the Yale laboratory it was found that as a matter of fact the sense of direction is remarkably accurate, a blindfolded subject making only 113 out of 656 possible errors. It was noted that the sounds of the right hemisphere were more accurately perceived than those of the left, those from the front more than those from the rear, and those from below more than those from above, variations which are probably due to the shape and direction of the pinna, and to the difference in the functional acuity of the two ears. Distance is estimated merely by the absolute intensity of the sound, but direction is gauged, according to Matsumato, by the relative difference between the intensities of the component sounds as heard by the two ears. This is such a delicate process that a ventriloquist can, by directing the attention of his audience to a given spot other than the actual source of the sound, and by certain studied modifications of the sound emitted, mislead the judgment into overruling the impressions on the sensorium of the observer and give rise to an absolutely false perception. There remains the fact that in certain atmospheric conditions, notably in fog, the sense of direction is greatly modified, and even lost, as sailors know to their cost. This fact would tend to show that senses other than hearing are concerned in completing the impression or at any rate in confirming or disproving the deductions based thereupon. — *Medical Press and Circular.*

SANITARY CONDITIONS IN THE CAMPS AT SAN FRANCISCO.

IN view of the scandals circulated about the condition and management of Camp Wykoff, Long Island, where the troops which took part in the Santiago campaign were taken at the close of the Spanish war, the report of Colonel Greenleaf, Medical Inspector of the Army, in regard to the camp established at the Presidio of San Francisco for the reception of the volunteer troops returning from the Philippines, is of more than ordinary interest and importance. The report, in part, is as follows:

This camp is now occupied by three regiments, the 3d Oregon, 1st Nebraska and 10th Pennsylvania, and the Utah Battery, aggregating about 3,500 men, the infantry regiments being in the section on the north side of the railway track and the artillery on the south side. The general health of the men is excellent, the sick report, exclusive of cases that were placed in the hospital immediately after arrival being 4.6 per cent. of the effective force and made up of such trivial ailments as mild affections of the air passages, indigestion, rheumatism, etc.

The fears that were entertained of serious illness owing to the climate and the scantily clad condition of the men have not been realized. Many of the men had thick clothing on arrival, and those who had none borrowed from their more fortunate comrades. Nearly all have observed the precautionary directions against exposure, and the comfortably heated quarters have given them shelter and lounging places when off duty.

The sanitary corps (civilian employés) has kept the latrine troughs, garbage and waste cans in excellent order, and the urine tubs, placed each night in the company streets have freed the camp-ground from defilement of this nature. The trough system for latrines is a perfect success, and these places, instead of being noisome sights, are now the show-places of the camps, the houses and their surroundings being neat and clean in appearance and entirely free from bad odor. Indeed, there is nothing about them that can offend the senses of sight or smell. The interior police of the camp of the 2d Oregon is not good. Kitchens, dining-rooms, bath-houses and lavatories are not kept tidy or clean, in spite of the orders reiterated each day by the colonel of the regiment.

The contrast between the work of the scavengers at the latrines and about the garbage cans with that of the soldier police in the quarters, kitchens and dining-rooms is very marked and fully sustains the opinion previously expressed in my reports, that the untrained soldier cannot be made to do the work of a scavenger, to which I must add, nor can he be made to keep himself or his surroundings clean. The food supply is abundant, well prepared, cooked and served. There is added to each one hundred of the regular rations twelve and one-half gallons of milk, ten pounds of butter and ten dozen eggs; this is furnished by the subsistence department under the act of Congress approved March 3, 1899, for "issues to enlisted men in camp during the periods of recovery from low conditions of health consequent upon service in unhealthy regions or in debilitating climates." It may truthfully be said that the food in this camp is much better in variety, quality and preparation than is found in the average hotel anywhere in this country. The medical records of the 2d Oregon Volunteer Regiment are in excellent condition; better, in fact, than any other volunteer regiment I have seen at muster out. I have not yet examined the records of the other regiments here. The medical and hospital property of this regiment has been transferred to the supply depot in San Francisco, and the regimental hospital furnished from the general camp supply I had furnished provided for the troops.

The detention camp at Angel Island is so far completed that one regiment can be accommodated at any time. The hospitals for contagious and non-contagious diseases are in position and equipped, a medical officer and detail of hospital corps men is on the ground, and a common dispensary is ready for service. Fortunately up to this date there has been no occasion to place any of the incoming transports in quarantine, and therefore the camp has not been used.

These camps of recruits have an occupancy of about 4,000 men, although this number changes from day to day, as transports leave for the Philippines and recruits come in from the east; the general health of the men is excellent, the sick report showing an average percentage of 5.8, of which 33 per cent. is vaccinia, 10 per cent. malarial in men who have had previous service in Cuba, and the remainder rheumatism, indigestion, venereal, etc. Boards of medical officers are in session for re-examination of the physical condition of the men who arrive, and many have been rejected; the exact percentage I have not been able to ascertain, but it is large enough to show that sufficient care is not yet exercised in the selection of recruits, especially for service in the tropics.

Four cases of typhoid fever have been taken from the general hospital from these camps, the history of each one of which I studied carefully as soon as it was reported, and all gave evidence of importation. Precautionary disinfection in the camp latrines has, however, been thoroughly practised, and I think there is no danger of this disease gaining any foothold. In order that errors in diagnosis may be avoided, medical officers are instructed to make careful study of all fever cases. Advantage was taken of the occurrence of these cases to introduce the trough system of latrines, and to do away with the dry earth-box system previously in use. The change will be completed in a short time. The urine tubs are in use in these camps also.

Complaint having been made of the presence of vermin in the bedding and clothing of some of the men, I had large caldrons for boiling water put up in the camps into which material so infected was ordered to be placed; these caldrons when not so used supply hot water for the laundering of the clothing of the men, galvanized iron wash-tubs having been furnished for this purpose. The food of the recruits is ample in quantity, but has little variety beyond the regular ration; it is fairly well cooked but indifferently served; mess tables had to be made from any lumber that was available in the two older camps, but in the new camp they were furnished with buildings. The latrines, garbage cans, etc., are emptied by men of the sanitary corps, and the kitchens, tents, etc., are policed by soldiers. There is a great difference in the cleanliness of these and the volunteer camps; here the police work of the recruits, under direction of regular officers, is well and thoroughly done, the kitchens and cooking utensils, the tents and the company streets being kept in excellent order.

All outgoing transports while in dock preparing for the voyage are carefully inspected by the medical superintendent, and immediately before sailing I also inspect them. In every instance they have been found in good condition. Before loading, estimates of troop capacity are made, with a view of securing proper air space, and assignments of troops are made in accordance with these estimates; the facilities for latrines, urinals, lavatories and baths are ample, and all are in good working order before starting. The capacity of the ships' galleys for cooking is determined, and when necessary extra galleys for troop service are put in. Fresh air is introduced between decks by wind sails, and electric fans keep it in motion. Ample ice-chest and cold-storage room is furnished, and the water supply and apparatus for replenishing it is tested. The question of substituting troughs for water-closets is being considered, since it has been found that the latter get out of order easily and do not work satisfactorily on long voyages with troops.

Correspondence.

AN INTERESTING TESTIMONIAL.

Brookline, Mass., August 16, 1899.

Mr. Editor: Among some papers of my grandfather I have come across a testimonial written, I think, by Dr. Waterhouse for one Martha Battles, expressing thanks for care received by her at the Massachusetts General Hospital as long ago as the year 1836.

It possesses some interest from its quaint phraseology and also historically as an early endorsement of the hospital, and therefore I send a copy of it to you for publication, if you think best.

Walter Channing.

Following is the testimonial:

"Dr. and Mrs. Waterhouse with Martha Battles thus express their thanks to Dr. Channing for his considerate, and successful attention to her, while under his care in the Hospital: — nor ought she to with hold the like expression of gratitude from Dr. Wyman, and the faithful Nurses.

"The extreme neatness-order-quiet and decorum of the noble establishment have corrected her former ideas of a public, charitable Hospital, which, instead of an odious Lazar-house, is, in truth a *Temple of Health*, dedicated to the honor of the good & glorious *Samaritan*."

Sunday 28 of August 1836.

To Dr. Walter Channing.

METEOROLOGICAL RECORD

For the week ending August 12th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,482; under five years of age 1,100; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 629, consumption 287, acute lung diseases 145, diarrheal diseases 466, diphtheria and croup 53, typhoid fever 46, whooping-cough 27, measles 15, cerebro-spinal meningitis 14, scarlet fever 5, erysipelas 3.

From whooping-cough New York 15, Boston, Nashville and Charleston 2 each, Baltimore, Cambridge, Lowell, Lawrence, Chelsea and Chicopee 1 each. From measles New York 11, Boston, Pittsburg and Providence 1 each. From cerebro-spinal meningitis New York 6, Baltimore 2, Boston, Cincinnati, Cambridge, Lowell and Holyoke 1 each. From scarlet fever New York and Boston 2 each, Pittsburg 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending August 5th, the death-rate was 24 6. Deaths reported 5,370; acute diseases of the respiratory organs (London) 159, diarrhœa 1,182, measles 128, diphtheria 91, whooping-cough 82, fever 35, scarlet fever 20.

The death-rates ranged from 12.7 in Croydon to 37.4 in Sheffield; Birmingham 24.6, Bradford 18.8, Cardiff 16.3, Gateshead 12.7, Huddersfield 19.2, Hull 18.3, Leeds 24.5, Liverpool 31.5, London 25.2, Manchester 29.0, Newastle-on-Tyne 27.6, Nottingham 28.1, Portsmouth 28.2, Salford 29.6, Swansea 21.1.

RECENT DEATHS.

ANDREW K. SMITH, M.D., an old army surgeon residing in New York, died suddenly of apoplexy, at Cranston's Hotel, near West Point, on August 14th. Dr. Smith entered the medical service of the U. S. Army in 1853, and was retired with the rank of Colonel in 1890. He was in the seventy-fourth year of his age.

NATHANIEL W. LEIGHTON, M.D., a prominent physician of the Borough of Brooklyn, New York, died August 12th, in the sixty-seventh year of age. Not long since he was President of the Fifth District Branch of the New York State Medical Association and one of the Vice-Presidents of the Association.

TUNIS L. SHENCK M.D., died at his residence at Van Pelt Manor, Borough of Brooklyn, New York, on August 15th, of Bright's disease. He was born in Flatbush, where he practised until ten years ago, and was fifty-eight years of age. At one time he was chief physician of the Kings County Hospital. He was a graduate of the Medical Department of the Syracuse University.

THE EFFECTS OF TRAINING.

A Study of the Harvard University Crews.

BY EUGENE A. DARLING, M.D., CAMBRIDGE.

This investigation was undertaken at the suggestion of the Harvard Athletic Committee, by whom it was felt that a knowledge of the physiological changes occurring during severe training would be of value, and that incidentally data might be obtained throwing light on the obscure subject of overtraining. It is intended to make a similar study of the effects of training for several other forms of athletic contests besides rowing, especially foot-ball and running. Since no similar research had, as far as known, been attempted, this first series of observations on the effect of rowing was regarded as tentative. It was doubtful how far the subject would lend itself to study and hence it was thought best not to attempt too much until the more promising lines on which to work had been determined. Much of the work has been somewhat barren of result, while in other directions unexpected facts have been learned and the necessity for further study revealed. For example, it early became apparent that one of the most important parts of the investigation would concern the nutrition and tissue metabolism, but for want of suitable apparatus and in the absence of a chemist to analyze the food and excreta, this part of the work was done only in the most superficial way. It is hoped that a subsequent investigation will include a much more complete study of these important points. The greater part of the work which was thought to be feasible this year was a study of the changes taking place in the heart and kidneys, and a series of observations on the weight and temperature and their relation to the general condition of the men. The observations covered the months of May and June, and hence included only the more strenuous part of the training period, for which all the men had been prepared by long preliminary work, as detailed below.

There were certain difficulties which limited the scope of the inquiry and which must be borne in mind in estimating the results obtained. The chief one was the impossibility of maintaining constant supervision over the men, and the consequent loss of much valuable information. This was not true, however, during the two weeks at New London, where the opportunities for observation were excellent. A second difficulty was that circumstances sometimes compelled the use of cruder methods of examination than would be necessary for the most accurate work. For instance, the most accurate method of determining the size of the heart and the method least liable to error from the "personal equation" is by means of the fluoroscope, but owing to the impossibility of setting up an elaborate x-ray machine at New London, one had to fall back on the less certain method of combined auscultation and percussion aided by the phonendoscope. A third limitation to the inquiry was the obvious one that all the observations had to be arranged so as not to interfere in any way with the main objects of the training, which were to learn to row and to get into the best possible condition. Consequently, nothing in the way of experiment could be attempted nor any examination which would fatigue the men or distract their attention from their rowing.

These limitations were unavoidable, but were counterbalanced in a way by the active co-operation of the coach and of the individual members of the crews. Their courtesy and interest were unfailing and alone made it possible to carry on the observations, involving as they did a considerable expenditure of time and a certain amount of irksomeness.

Preliminary training. — The large number of candidates who began training in the winter were gradually weeded out by a process of natural selection, based on numerous trial races, until but sixteen remained. These men were organized into two crews late in April, and practised daily until early in June. Shortly before going to New London a new man was taken from one of the Weld crews, and five of the squad were dropped. The remaining twelve comprised the two crews — the eight-oar and the four-oar — which took part in the races, and most of the statistics of this paper refer to them. The observations on the five who stopped training early in June were eliminated, so that more accurate comparison could be made.

Of these twelve men all had done considerable previous rowing in their class crews or in the Weld crews. Four had rowed on former Varsity crews and one had been a substitute. Several had begun rowing in preparatory schools. Six out of the twelve had played football and two had practised running. The period of active training for these sports had been from two to six years, so that all the men may fairly be called trained athletes, and the changes effected by training would not be expected to be as marked as in the case of inexperienced men.

The previous health of all the men had been good with one exception, who gave a history of typhoid six years ago and rheumatism a year later.

General statistics. — The following table gives in brief the ages, weights, heights, chest and abdominal measurements and vital capacities of the lungs of the individual members, with averages for the eight and four, and, finally, the averages for the entire squad:

Table I.

No.	Age.	Weight May 9-17.	Height.	Chest measurements.			Circum. of abdomen.	Vital capacity. Cu. ins.

I. GENERAL SKETCH OF THE TRAINING.

Daily rowing. — During May and the first ten days of June the daily exercise consisted of rowing on the Charles in the latter part of the afternoon. The distance covered varied according to circumstances from five to eight miles, occasionally more. At New London there was added a short morning row of two to four miles. Between the middle of May and the race there were five time-rows — three on the Charles of three and three-eighths miles each, and two on the Thames over the four-mile course. These time-rows were designed to accustom the men to rowing long distances at high speed and to enable the coach to judge of their form and endurance, but incidentally they afforded excellent opportunities to study the effects of long-continued exertion, and were, moreover, striking demonstrations of the effects of training. The earlier time-rows, though shorter than the later ones, were much more exhausting, and their effects on the hearts and kidneys — the organs showing most evidence of strain — were considerably greater.

For the purposes of this inquiry, however, the time-rows had to be regarded as factors disturbing the regular process of development which might be expected were the daily exercise uniform or slowly increased, and hence it became necessary to divide the observations into two parts, the first directed to the changes in the daily condition, eliminating the effects of the time-rows as far as possible, and the second directed to the immediate effects of the time-rows.

Diet. — The diet allowed was a very generous one, consisting of a hearty breakfast at 7.30, lunch at one and dinner after the evening row. For breakfast the fare consisted of fruit, oatmeal or shredded wheat, eggs, some form of meat, bread and butter, potato and milk. At noon there was cold meat, potato, bread and butter, marmalade, preserved fruit and milk. Dinner comprised soup, occasionally fish, roast beef or some other hot meat, several vegetables, bread and butter and a simple dessert. No tea or coffee was allowed, but ale or claret was permitted at dinner, also water in small amounts as desired. During the last week before the race each man received a dish of calves'-foot jelly with sherry wine after the morning row, and a light lunch of oatmeal, milk and bread was served at four o'clock in the afternoon.

Sleep, bathing, etc. The ordinary allowance of time for sleep was nine hours, from ten to seven. General plunge baths were prohibited, but after rowing the men were allowed a cold shower bath in Cambridge and a bucket bath (for want of a shower) at New London.

Besides rowing the men indulged in very little exercise. While at New London a five-minute walk before breakfast, an occasional game of quoits or spasmodic efforts to play baseball were the only other forms of exercise indulged in. When not rowing, sleeping or eating the men passed the time in reading, writing or in pure and simple loafing.

II. EFFECTS OF TRAINING.

Weight. — It has long been recognized by athletic trainers that the weight is one of the best indicators of condition. The average weight of the eight men constituting the crew from May 18th to June 29th is shown in Chart I.

During the first ten days of this period there were no marked variations, and in spite of two hard time-rows the average on May 29th was exactly the same as on May 18th, 171.4 pounds. Beginning May 30th, when there was a third time-row, there was a steady fall in weight for a week. The weather at this time

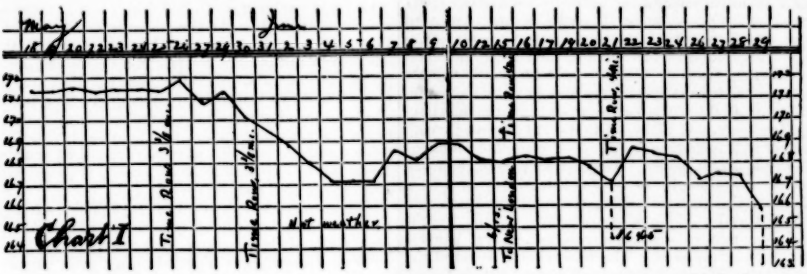

Chart I. Average Daily Weight of Varsity Eight.

was very hot and oppressive, and owing to the fact that the crew rowed for a few days on Spy Pond, Arlington, there was much delay in getting dinner. These two factors, added to the hard work the men were then doing, contributed to the fall in weight. From June 6th until the day of the race the average was very constant, fluctuating between 167 and 169 pounds, although individuals showed more or less variation. Losses in some men were usually balanced by gains in others. Chart II illustrates the range of variation in three of the crew. In the case of No. 7, whose condition was uniformly good, the variation was slight and, leaving out of consideration the sharp fall during the time-row and race, amounted to but three pounds. In Nos. 6 and 3, on the other hand, the range of variation was ten and eight pounds respectively. No. 6 began hard training in April and was somewhat slower in getting down to his normal training weight than the others. The sharp fall in No. 3's line between May 30th and June 2d was accompanied by some insomnia and general malaise, but unfortunately he was not under immediate observation at the time. One of the commonest causes of fluctuation in weight was diarrhea. In several instances slight attacks caused a fall of three or four

pounds in twenty-four hours, though in every case this was quickly restored soon after the diarrhea ceased.

Tables II and III show the effect of the last time-row and of the races on the weight. The preliminary loss means that which is always noticed during the twenty-four hours before a race. It may be attributed to nervousness, affecting the appetite and urinary secretion. This preliminary loss, as might be expected, was considerably greater before the race than before the time-row, being $12\frac{1}{4}$ and $6\frac{1}{4}$ pounds respectively, while the actual losses during the time-row and race were nearly the same, $20\frac{3}{4}$ and 22 pounds respectively.

Through an oversight, the weights of the Varsity four-oared crew were not recorded during the last two weeks of training. A comparison of their weights immediately before and after the two-mile race showed an aggregate loss of 13 pounds, averaging $3\frac{1}{4}$ pounds.

Compensating for the rapid loss before and during the time-rows and races, there was noticed after those events an equally rapid recuperation; this is shown in Table IV, in which are given the total losses and corresponding gains for the time-row of June 21st. Every man recovered all or more than he had lost inside of twenty-four hours.

A loss of several pounds during prolonged exertion does not by any means imply an undue degree of exhaustion, provided the individual is in good condition. The men who lost most were in fully as good condition as their companions both before and after the race. It is generally accepted on experimental grounds that during active exercise the energy is largely if not wholly derived from the oxidation of fat and glycogen, and that the muscles themselves are not used up in the process. The end products of this combustion — chiefly water and carbon dioxide — are rapidly excreted through the lungs and skin. The loss of weight represents very closely, therefore, the amount of fuel used up. Hence the man who has an adequate supply of reserve fuel in the form of fat and glycogen is in better condition to withstand a prolonged exertion than one who is deficient in

TABLE II. Loss of Weight in Time-row of June 21st.

those substances. This corresponds with the experience of all athletes. There is always a loss of weight during the early part of training, while a man is getting rid of superfluous fat, but every athlete knows that when a certain point is reached — his so-called "weight in training" — any further reduction is accompanied by a feeling of lassitude and an incapacity to sustain prolonged exertion without excessive fatigue. This form of over-training, known as "staleness," is in all probability due to a deficiency of reserve fuel. These facts emphasize the importance of maintaining at a proper proportion the fat and carbohydrate constituents of the diet instead of sacrificing them for an excess of nitrogenous material — a mistake which is undoubtedly often made, and which will be discussed more in detail later.

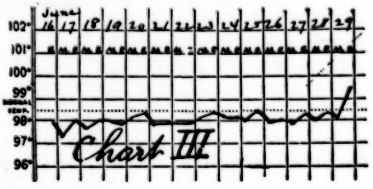

CHART III. Temperature Chart of Entire Squad.

Temperature. — The temperatures were taken in the mouth twice daily, at 8 A. M. and 9.30 P. M., during the last two weeks of training. The chief points brought out by the routine readings were the great variation in individual cases and the persistent tendency to subnormal temperatures. The average for the entire squad remained near 98° F., as shown in Chart III.

A few individuals maintained approximately a normal average of 98.5°, but the majority showed wide variations. It was not uncommon to find a temperature of 96° in the morning and 98° or more in the evening in the same man. Charts IV and V are fair sample charts.

The individual variations could not be shown to have any definite relation to the general condition beyond the coincidence that those men who varied most in weight also varied in temperature. The body temperature is dependent on so many circumstances that variations within limits are to be expected. The heat production during muscular and other metabolic action is constantly balanced by the heat loss in warming the expired air, the urine and feces, by evaporation of perspiration and by conduction and radiation from the skin. During training the greater part of heat production by muscular action (supposed to be its main source) is confined to a comparatively brief portion of the twenty-four hours and during that same portion the heat loss is also great. It is not surprising that the heat balance is not stationary and the charts show that in fact in the majority of cases it is not maintained at a fixed point.

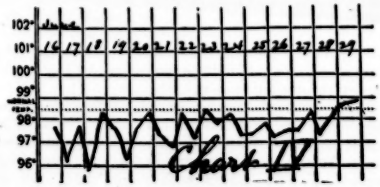

CHART IV. Temperature Chart of No. 8.

On the day of the races the temperatures were taken three times, first, at 8 A. M., second, while the men were dressing for the race, and finally, from ten to fifteen minutes after the race while returning to the quarters in the launch. There was an average preliminary rise in temperature, corresponding to the preliminary fall in weight, amounting to about 1.5° F., followed by a slight rise of .2° during the four-mile race. In the case of the four-oared crew the average preliminary rise was .7° and a further rise during the two-mile race of .7°. A glance at the Table (V) shows that on the whole those men who had the greatest preliminary rise had either a stationary or falling temperature during the race (Nos. 2, 4 and 5). The other extreme was seen in No. 9, who had a preliminary rise of only .2° and a rise during the race of 2.6°. In several instances the net variation was very slight.

It was hoped that the temperature observations would throw some light on the remarkable results obtained by Drs. Williams and Arnold in their observations of the Marathon runners.[1] They found a uniform drop during that race (a 25-mile run) of 2° to 5⅛°. That race, however, was run in the middle of April at a temperature of 44° F. and against an easterly wind — the conditions all favoring rapid cooling by conduction and evaporation. Furthermore, the temperatures were all taken in the mouth and after nearly three hours of rapid breathing of air at 44° F. it is not unreasonable to assume that the mouth cavity may have been cooler than the body generally. One cannot accept as proved their assertion that after prolonged exertion the temperature is invariably lowered. It is the same with their implication that a subnormal temperature during training means "staleness." This idea was apparently based on the single observation that the temperature of one of the contestants was 97.5° before and 97° after a practice run; that the man was advised to rest and to partake of more carbohydrates; that on the morning of the race his temperature was 98.2°, and finally that he was among the winners. This observation proves nothing except that a rest and some carbohydrates are good things before a race. The temperature variation was quite within normal limits. If subnormal

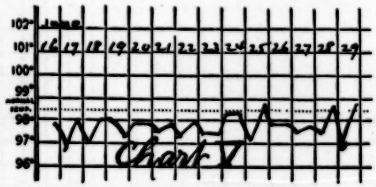

CHART V. Temperature Chart of No. 4.

[1] Philadelphia Medical Journal, iii, 1,233.

temperature means overtraining, then nearly every man in the Harvard crew squad was overtrained at one time or another during the last two weeks before the races, a statement which certainly would not be borne out by the other facts in their condition nor by the vigor which they all displayed during the last time-row and especially during the races. The rise of temperature observed just before the races certainly did not mean a rapid recovery from a condition of "staleness," but simply indicated that for some reason,

probably a nervous one due to excitement, the heat production was greater than the heat loss. During the boat races, which were rowed on a clear, sunny day at a temperature of about 80° F. and low humidity, the conditions were favorable for rapid heat loss by perspiration and radiation, so that the excessive heat production which, according to all physiological experience, must have taken place was readily dissipated and the temperature balance maintained. On the whole we must admit that a subnormal temperature, while of possible significance, cannot yet be regarded as a positive proof of overtraining.

(To be continued.)

A SAFE AND QUICK METHOD OF JOINT AND BONE FIXATION.[1]

BY EDWARD A. TRACY, M.D., BOSTON.

IN this paper will be briefly described a method for quickly producing fixation of the joints and bones. The fixative material employed is wood fibre reinforced with gauze. It is made in large sheets of two thicknesses. It is adaptable to all cases of surgical splinting. The fixation is produced by moulding upon the limb a properly shaped piece of the splint material, (this piece may be termed the "splint-blank") and bandaging it snugly to the limb. When moulded and bandaged properly the moistened wood fibre produces immediate fixation. Sometimes, when great strain on the material is apprehended, as, for example, in hip-joint fixation, it is advisable to apply a double splint-blank.

Before describing the technique in detail of this method of fixation, I shall define a term already mentioned — splint-blank. The term is newly coined. My apology for it is that it is a term of convenience in the descriptions that follow. When it is desired to immobilize a limb or a part of it by this method we cut a paper pattern so as to embrace the limb in the same manner we wish the completed splint to embrace it; this paper pattern we lay on a sheet of the splint material and we cut from the sheet a piece following the outline of the pattern; this piece is the splint-blank; when moistened with water and bandaged over the limb it forms the splint. A splint-blank, therefore, is a piece of splint material cut in such fashion that when moistened it can be bandaged over the part for which it is intended, producing fixation of the part.

In describing the manner in which fixation of the various joints and bones is produced by the new method, I shall proceed in the following order: (1) The fingers; (2) the thumb; (3) the wrist; (4) the bones of the forearm; (5) the elbow-joint; (6) the arm; (7) the shoulder-joint (humeroscapular); (8) the claviculoscapular joint; (9) the cervical spine; (10) the ribs; (11) the hip-joint; (12) the hip and knee joints; (13) the knee; (14) the leg; (15) the ankle; (16) the toes.

(1) *The fingers.* — The fingers together can be immobilized by bandaging a piece of moistened splint material folded over the palm and back of the hand. I have done this in the treatment of multiple lacerations, getting quick union because of the immobilization produced, and giving the patient comfort because of the protection afforded the injured parts. This use of wood-fibre material to produce immobilization of the soft tissues during healing originated with Dr. Fletcher, of South Boston. His experience, related orally, led me to use the material for this purpose.

Fixation of a separate finger is produced by moulding the correctly shaped splint-blank over the back and sides of the finger to be immobilized and the back of the hand. This bandaged over the finger and hand produced a complete fixation of the finger. For cases of finger fixation the thinner sheet of the splint material should be used. I have produced fixation of the separate fingers for joint disease and compound fractures.

(2) *The thumb.* — The thumb can readily be immobilized by bandaging to it and the hand a splint-blank that encloses the thumb and the back and front of the hand, taking care the cross-palm lines in the hand are not covered by the material, which could thus interfere with flexion of the fingers.

[1] Paper read to the New York County Medical Society, November 21, 1898.

I have employed this method in immobilizing dislocated and contused thumbs.

(3) *The wrist.*— A perfect fixation of the wrist-joint can be produced by bandaging over the wrist, hand and forearm a moistened splint-blank cut so that it covers the back of the hand, wrist and forearm. I have frequently produced immobilization of the wrist in this manner in the treatment of sprains, fractures and joint diseases. The fixation is absolute, and the splint readily permits of the most efficient treatment of Colles's fracture: retention of the fragments until reunion takes place; passive motions of the fingers and thumb from the first day, and careful passive motion of the wrist from the fifth day.[2]

(4) *The bones of the forearm.* — The bones of the forearm are immobilized by bandaging a moistened splint-blank cut so as to lie over the back of the forearm and hand and over the palmar surface of the forearm; or by bandaging two splint-blanks, one cut so as to lie over the dorsal surface of the forearm and hand, the other over the palmar surface of the forearm, and cut so as to overlap the other at either radial or ulnar side. This forms a casing for the forearm and permits of efficient maintenance of the fixation of the enclosed bones.

In a case of fracture of the ulna, upper third, a dorsal splint moulded on the forearm was found sufficient to produce fixation. In a case of fracture of the ulna produced by the kick of a horse a splint was moulded over the external aspect of the flexed arm, the dorsal aspect of the forearm and hand, producing in this manner immobilization of the elbow and wrist joints; a splint was also moulded over the palmar surface of the forearm; this combination produced absolute immobilization of the radius and ulna, deemed desirable in this case, an old man with double cataract and atheromatous arteries.

In seventeen days there was union; on the twenty-first day the angular splint was cut across at the elbow, so that it became a simple dorsal forearm splint. For safety this was left on eight more days, and twenty-nine days after the beginning of treatment the patient was discharged well, with normal mobility; the callus but moderate in size.

(5) *The elbow-joint.*— Fixation of the flexed elbow-joint is readily effected by bandaging a moistened splint-blank, cut so as to embrace the arm, and the dorsal and ulnar aspects of the forearm, the forearm being in the semi-prone position. This splint form has served well in several cases for fixation of the elbow joint after reduction of dislocations, and in cases of fracture into the joint. The joint can be fixed at any angle, the shape of the splint-blank varying with the angle.

(6) *The arm.*— Fixation of the arm for fractures of the shaft of the humerus.

Fracture of the surgical neck. — I have treated several cases of fracture at the surgical neck of the humerus by moulding a splint-blank over the shoulder and external aspect of the arm (a shoulder cap), and another splint-blank to lie over the inner aspect; these were bandaged over the arm and the arm thus splinted was bandaged to the side of the body, the elbow being flexed and the wrist supported in a sling. This method of splinting for fracture of the surgical neck is essentially Hamilton's. He used leather. Wood-fibre material is preferable because it is much easier to manipulate and is porous, a decided advantage over leather.

Fracture of the shaft near the elbow-joint. — In a recently treated case of transverse fracture of the shaft of the humerus just above the elbow-joint in which the lower fragment was tipped forward so as to allow of considerable hyperextension, the fracture was reduced by pulling on the elbow-joint in the direction of the line of the shaft and at the same time flexing the elbow to an acute angle. The fragment was kept in this position by keeping the elbow to an acute angle and a moistened splint-blank cut so as to embrace the tip of the shoulder, the arm and the forearm in this position was moulded and bandaged over the parts. The splinted member was then bandaged so as to lie over the front of the chest wall. This splint was worn for sixteen days, then discarded for a sling. A few weeks of passive motion, massage, and weight-carrying restored the arm to perfect functional use.

(7) *The shoulder (humeroscapular joint).* — Fixation of the shoulder-joint is readily obtained by bandaging to the arm a moistened splint-blank, cut so as to lie over the shoulder and embrace the arm, and bandaging the splintered arm to the side of the chest, the hand and forearm lying across the front of the chest, under the bandage. The latter bandaging is of importance. When viewed from the front or back this bandage should have the appearance of a triangle, with its apex in the sound axilla, one end of its base over the top of the shoulder, the other at the elbow.

The splint-blank can be moulded over the shoulder by cutting a slit or two in its upper border toward the point that lies over the top of the humerus; this allows an overlapping of the redundant portion of the splint material and permits it to be moulded over the shoulder.

(8) *The claviculoscapular joint.* — Fixation of this joint can be produced by moulding a splint-blank cut so as to lie over the clavicle, the scapula, and to a line on the chest about five inches below the clavicle. This splint is kept in close apposition to the parts, and thus immobilizes the claviculoscapular joint, by means of an elastic webbing loop buckled over the chest. The apparatus is fully described and illustrated in the *Boston Medical and Surgical Journal.*

(9) *The cervical spine.* — The cervical spine can be immobilized by moulding several superimposed splint-blanks cut so as to lie over the occiput, the back of the neck, and the upper back. Le Page's liquid glue should be spread between the several splint-blanks, and the superimposed blanks bandaged singly over the parts. This is somewhat difficult because of the great normal mobility of the shoulder. To aid in the fixation of this splint form by bandaging it, it is well to place a roller compress in the hollow over the neck, of course outside the splint.

In a case of trauma in the immediate region of the left occipito-atloid articulation, I produced fixation of the cervical spine in the manner described with great comfort to the patient.

(10) *The ribs.* — Fixation of the ribs in the ordinary sense is an impossibility. An approximation to it is effected by the swathe, or adhesive plaster. In cases of fracture of the ribs neither of these protect the injured parts from pressure. In the treat-

[2] See paper on Colles's Fracture in Journal of the American Medical Association, November 20, 1897.

ment of fractured ribs I mould a splint-blank to lie over the fracture and to rest on the sound ribs; this splint, when held in position by a snugly applied swathe, is a source of comfort to the patient because of the protection it gives the injured parts. I have treated broken ribs in every situation of the chest in this manner, always satisfactorily.

(11) *The hip-joint.* — Fixation of the hip-joint is readily produced by bandaging a splint-blank cut so as to lie over and clasp the side of the body from the level of the base of the scapula, and the thigh to the knee. A double splint-blank should be used. The manner of bandaging this splint form to the body is important. The roller should be applied first so as to embrace the body around both hips for several turns; then in figure-of-eight style around the splinted thigh and body; then down the thigh; finally a bandage should be applied around the body and upper part of the splint. The splint I here exhibit was moulded and applied in a case of traumatic synovitis of the hip-joint in a half-hour's time, without assistance. These splints are durable, some having been worn in tubercular cases for more than twelve months.

(12) *The hip and knee joints.* — Fixation of the hip and knee joints simultaneously is seldom required. It can be produced by means of a splint-blank like that for hip-joint fixation — but made longer, so as to embrace the leg below the knee. I have produced such fixation in a case of tuberculous disease of both joints (the left limb) with excellent result.

(13) *The knee-joint.* — Fixation of the knee-joint extended or at any angle is readily produced by the use of wood-fibre splint material. This fixation can be effected by several procedures, each of which will be described.

Fixation of the extended knee. — The simplest method of producing fixation of the extended knee is by bandaging a moistened splint-blank cut so as to lie over the posterior and internal lateral aspects of the leg and thigh — from a half-inch above the ankle to near the pubic bone. The length of the splinting is important, because the further it extends in both directions from the joint the greater is the leverage obtained for controlling the joint. This splint rightly made and applied gives an absolute fixation of the knee-joint. This immobilization can be efficiently maintained by keeping the splint snugly bandaged to the limb. In many cases of traumatic synovitis of the knee-joint I have used this form of splint. I believe that efficient fixation with non-use of the joint cannot be too strongly advised as soon as possible after such injury is received by the knee. This treatment is *curative* and would prevent many of the cases of chronic synovitis, with subacute exacerbations, so frequently met with in practice. The previous history of those cases is that they had no treatment at the time of injury, or that the treatment was manifestly inefficient. It is, I know, a serious matter to insist upon a person who is the main support of a family leaving work for a month. It should be done rather than the patient run the risk of being handicapped in life's struggle by a weak and chronically diseased joint. I would not be understood as advocating excessive splinting, which can be injurious, especially in cases associated with hysteria. After-treatment can remedy the damage done in the rare cases of over splinting — but no treatment can repair the damage done by inefficient treatment directly after the accident.

These remarks about the importance of efficient fixation in the treatment of traumatic synovitis of the knee-joint are applicable to similar injuries of the shoulder-joint. Cases of chronic synovitis of the shoulder are met with having a history of neglect of treatment or very inefficient treatment at the beginning of the trouble. Putting the arm in a sling or strapping with adhesive plaster does not immobilize the shoulder-joint and therefore is inefficient treatment.

The splint form above described I have found very efficient in cases of traumatic synovitis; also to produce fixation after operations on or near the joint, as the removal of movable bodies in the joint and hydroma over the knee-pan.

For long-lasting immobilization, as that required in the treatment of tuberculosis of the joint, splinting that may be described as an encasement of the limb is preferable. This is done by moulding two lateral splint-blanks cut so as to enclose the limb from a short distance above the ankle (about one-half inch) to as near the perineum as possible, one slightly overlapping the other. To mould these accurately over the limb, it is necessary to incise the splint-blanks where there is a redundancy of material; the incisions if properly made allow the redundant material to overlap, and the splint-blank to be moulded into apposition with the limb's surface, and do not weaken the splinting. This method of splinting the knee is superior to the plaster-of-Paris method for the following reasons:

First. The fixation is superior because no cotton batting or other padding is between the fixative appliance and the skin. The nearer a fixative appliance is to the parts to be immobilized the better the resulting fixation. This is a principle of mechanics to be remembered — not ignored.

Second. The splint can be removed and the joint inspected at any time by the easy procedure of unwinding a bandage; the appliance is not injured by such removal.

Third. Subsidence of swelling or tissue atrophy does not impair the immobilizing properties of this splint, for when such occurs, the resiliency of the splint material permits the immediate production of complete fixation by applying the retentive bandage more snugly.

Fourth. The splint is more durable; at the end of eight months it is as efficient as when first applied.

Fifth. The splinting is much lighter, a fact gratefully noted by patients who had before been treated by plaster-of-Paris.

Sixth. The splinting is cheaper.

Fixation of the flexed knee. — Fixation of the knee flexed at any angle is readily produced. A double splint-blank cut so as to lie over the inner aspect and embrace the thigh and leg in that position in which we desire to immobilize it, is bandaged to the parts; this produces fixation.

I have produced fixation of the knee in the flexed position, in the treatment of broken leg-bones, in cases where relaxation of the leg muscles was indicated, the leg-bones being immobilized as described in the next paragraph.

(14) *Fixation of the leg-bones.* — Fixation of the leg-bones is produced by bandaging a splint-blank cut so as to embrace the leg, except its posterior aspect, and extending from the lower end of the front of the tibia to its upper end. This splint serves admirably in the ambulatory treatment of broken legs. No

vague theorizing is necessary to explain why the broken shaft being restored to its right form the splint holds it there, and the body-weight is transmitted through the shaft thus restored to its functional integrity.

(15) *The ankle-joint.*— Fixation of the ankle-joint is readily produced by means of the wood-fibre splint material. I will describe briefly two procedures. A splint-blank can be cut so as to lie over the inner aspect of the leg, ankle and palmar surface of the foot; this if cut properly, when moistened can be bandaged snugly over the parts, thus producing fixation. Another way is to cut a splint-blank from a thin sheet of the material — the splint-blank shaped so that when moistened it will lie over the internal aspect of the lower part of the leg, the palmar surface of the foot, and the external aspect of the ankle and lower part of the leg. This when bandaged over the foot, ankle and lower part of the leg produces a perfect fixation of the ankle-joint.

(16) *Fixation of the toes.* — The big toe can be immobilized by moulding a moistened splint-blank cut so as to embrace it and the dorsal and palmar surfaces of the foot, and bandaging it snugly over the parts. To produce individual fixation of the remaining toes is impractical; they must be immobilized together. The toes are readily immobilized by moulding over them and the foot a splint-blank cut so as to extend from above the heel along the sole of the foot to about two inches beyond the toes; laterally it should extend about three inches beyond the outline of the anterior half of the sole. In moulding this splint-blank over the toes and foot, first the lateral projections of the blank are folded over and moulded upon the anterior half of the foot, then the projecting piece of the blank in front of the toes is brought (lifted) upwards and folded over the others. The whole is snugly bandaged over the foot and ankle. The resiliency of the splint material permits the piece moulded over the heel to be bent downwards to permit of the easy removal of the splint. It can readily be reapplied. This splint form produces an efficient immobilization of the toes. It is illustrated in the *Boston Medical and Surgical Journal*, November 21, 1895.

The method of joint and bone fixation here described is designated safe, because the parts immobilized can be inspected at any time by simply unwinding the retentive bandage; quick, because a few moments are sufficient for applying the splint material in most cases. The efficiency of the immobilization is worthy of consideration. I do not recognize as fixative in the correct usage of the term any material that necessitates the use of cotton batting or other padding between it and the skin.

THE PEARL A URINARY CALCULUS. — According to certain naturalists the pearl is a pathological product, an attempt to get rid of some foreign body, a grain of sand, fragment of shell or something of the kind, which falls into the genital gland or vicinity, and is thus in fact merely a renal or urinary calculus, and the oyster an unfortunate mollusc victim of nephritic lithiasis. An article in the *Revue des Deux Mondes* describes the efforts that have been made to cultivate pearl development by trephining the shell and introducing a tiny artificial pearl as a nucleus. — *Journal of the American Medical Association.*

Clinical Department.

A CASE OF SARCOMA OF UTERUS; REPEATED OPERATIONS; RECURRENCE; DEATH.[1]

BY S. J. MIXTER, M.D., BOSTON.

M. J. C. came to the Massachusetts General Hospital on February 21, 1890, for the first time and gave the following history: Born in Massachusetts; living in West Gardner. Married; fifty-four years old. Family history negative. Has had two children, and since the birth of the last one, thirty years ago, that is, when she was twenty-four years old, has had three miscarriages without known cause. She began to notice a slight flowing at irregular intervals about ten months before her entrance to the hospital. She has had slight pain in the pelvis. She says that something came down into the vagina about six months ago; that she pulled on it and tried to get it out, but it bled and pained her. A large lobulated, fibrous polyp was found with a pedicle attached to the posterior wall of the os uteri.

On February 25th she was operated on under ether. The pedicle of the mass was cut with scissors. Pressure over the uterus led to the birth of two more polyp, and other small ones were removed by forceps through the vagina. There was considerable hemorrhage. A hot corrosive douche was given and the vagina and uterus were packed with gauze. The convalescence was uneventful. She was discharged on the sixth day after operation.

Dr. Whitney reported on February 25, 1890, as follows: A lobulated, moderately firm and translucent growth, the lower surface of which was necrotic. It was composed of fibrous tissue in part, and between the bundles of this was a richly-cellular tissue, in which were evidently the remains of tubular glands; a polypoid growth from the mucous membrane chiefly.

On May 12, 1893, she returned to the hospital. A few months before a vaginal discharge accompanied by backache had set in. Examination showed a round, soft mass, completely filling the vagina. On the sixteenth this was removed, and she was discharged on the twenty-fourth.

A year later she returned with a soft, pulpy mass about the size of a lemon protruding into the vagina. She was not in robust condition, having lost a good deal of blood. A soft, pulpy, purplish foul mass was removed and the uterus curetted. She was advised to return for hysterectomy if she had further trouble.

She returned in a year, complaining of bleeding and a sense of weight in her pelvis. There was a large, spongy, pedunculated mass, nearly as large as a grapefruit, in the vagina, which was removed.

Almost exactly a year later she again returned. A week before entrance a polyp had protruded an inch beyond the vulva and had bled considerably. When she went to stool the polyp went back, she thought, and the bleeding stopped. On examination the cervix was felt as a soft ring lined with an irregular growth. A large amount of material which looked like fish-spawn, only more translucent, was removed. Dr. Whitney reported a small polypoid, or rather papillary-looking mass, composed of a myxomatous base

[1] Read before the Obstetrical Society of Boston, February 21, 1899.

with enlarged and irregularly-shaped gland-like involutions covering the surface; a mucous and adenoid polyp, not malignant."

Returning a year later, she said that three weeks before a soft mass, which had protruded from the vulva for a week or more, broke off, causing considerable bleeding. Two or three days later another mass protruded. In the vagina were found numerous polypi and some sloughing stumps. The discharge was foul. The masses were torn away with forceps and the uterus and vagina curetted. A large teacupful of cyst-like masses was removed.

Five months later she returned with a soft, dark tumor protruding from the external os, which bled on slight pressure. A tumor, the size of two fists, and made up of soft, friable material was removed. This was the first time that sarcoma was reported.

She came back again two months later, that is, last February, having noticed a lump in the neck of the uterus. She had not been free from pain since leaving the hospital. Hysterectomy was performed, the fundus being amputated low down on the cervix. The disease had infiltrated the pelvis and also appeared on the intestines.

She gained eight pounds in the next two months and a half, but in May she noticed that the nozzle of her douche entered the vagina with difficulty. She entered again and a polyp which filled nearly the whole vagina was removed.

In August, however, she came back, and several sarcomatous masses the size of hen's eggs were shelled out of the vagina with hands and scissors. Microscopical examination of one of these showed a typical sarcoma made up of round and spindle cells.

She began to have pain again in September, and the growth appeared at the vulva on October 25th. On the 25th a large, foul, sloughing mass the size of a banana was removed from the vagina. She remained in the hospital receiving the Coley treatment until her death, which occurred about the middle of November.

The above case is reported for two reasons: (1) because sarcoma of the uterus is a comparatively rare disease, and (2) to show the necessity of early radical operation in all cases of recurrent uterine growth or hemorrhage, whatever may be the result of the microscopical examination.

In all, this patient was operated upon eleven times by six different surgeons, including myself, and it was not until the seventh operation that the microscope showed anything malignant. Had the uterus been totally removed after the first or even second recurrence the result might possibly or even probably have been a cure.

Dr. Whitney was the first to my knowledge to insist on hysterectomy in cases of recurrence, whatever might be found by the pathologist, as his experience shows that the growth may be clinically malignant, or at least may become so.

It is due to the various surgeons in charge of the case to state that until the disease was practically beyond radical treatment, the patient refused to have the uterus removed. The later operations were entirely for the relief of symptoms, hemorrhage and sloughing. The extreme rapidity of growth and the great amount of sarcomatous tissue that formed before sloughing took place were striking features of the case.

A CASE OF MYXOSARCOMA OF THE UTERUS AND VAGINA, FROM THE SERVICE OF DR. J. G. BLAKE AT THE BOSTON CITY HOSPITAL.[1]

BY E. H. MACKAY, M.D., BOSTON,
Gynecological House Physician.

On June 21, 1898, the following patient presented herself for treatment at the Boston City Hospital. The case is reported on account of the rarity of the disease in this location, and also on account of its pathological interest. The salient points are as follow:

Mrs. C., age sixty-three, married twenty-five years. She was operated upon at the Massachusetts General Hospital, May 18, 1898, and the following is taken from their records:

"An eroded fungoid mass springing from cervix occupied the vault of the vagina; limits could not be defined by the finger. Discharge very foul. Large masses removed by fingers, tissues found infiltrated and no exhaustive dissection made; discharged June 11th."

Diagnosis. — Myxosarcoma.

The complaint is, that for the past six months there has been considerable loss of flesh and strength, and recently there has been a constant sharp pain across the lower abdomen and small of the back, and a more or less bloody discharge from the vagina.

While the patient was being prepared for examination, a tumor was expelled from the vagina. Macroscopically, it resembled organized blood clot. Its origin was from the anterior vaginal wall, its former attachment being readily felt. Further examination revealed the presence of three or four more tumors higher up, varying in size from that of a lima bean to that of an English walnut. These masses were removed manually and with the curette by Dr. Blake. The pathologist's report of the specimen was: "Mixed-cell sarcoma."

The patient was discharged in twenty-one days relieved.

The subsequent history of the case could not be obtained as the patient left the country immediately after her discharge from the hospital and no relatives or friends could be found to give further information concerning her condition.

The recognition of this varity of new growth in the vagina belongs to the very recent times. It appears in the form of a circumscribed round tumor in the submucous tissue, and also as a diffuse superficial degeneration of the vaginal walls.

Without question, instances of the first sort may without close historical examination be ranked with fibromyomata and those of the vagina may develop in a similar manner to the rare forms of papillary sarcoma of the cervix, into polypoid papillary excrescences.

It is interesting to note at what an early age this growth has appeared in the few recorded cases, and that in a single case it is stated that at birth a tumor the size of a pea was found between the labia. In one case the age was two years, in another, two and one-half years, and in two others, three years.

The anterior vaginal wall was entirely or largely the seat of the growth in six instances, the posterior wall twice, the right lateral once, and the entire circumference once.

In five reported cases in children the first sign was

[1] Read before the Obstetrical Society of Boston, February 21, 1899.

the appearance between the labia, without subjective symptoms, of a small polypoid tumor. When the growth was accompanied by increased secretion, atypical hemorrhages, dysuria, and bearing-down sensations, then it had attained considerable development.

When suppuration and extension to neighboring organs had occured, then the symptoms were dependent on the local changes, and in children especially the pressure symptoms on the pelvic organs were very marked.

A Russian observer reports two cases. The first concerns a strong multipara in whom two years previously there had appeared a small tumor on the posterior vaginal wall near the fornix which slowly increased in size, resisting all local measures. The tumor was about the size of a half dollar and was ulcerated upon its surface.

Prof. Kieter extirpated it and it proved to be a spindle-cell sarcoma lying in the mucous membrane, and extending scarcely at all into the submucosa. Recurrence speedily set in.

Kieter reports a case of similar nature which was seen in the Moscow Marien Hospital, the patient being a female seventeen years old. On the post-vaginal wall was a soft, easily torn tumor the size of a goose egg, and in four months after extirpation it had recurred, and was the size of the fist. The very anemic patient died shortly after the second operation.

Spiegelberg reports a case of fibrosarcoma of the lower portion of the vaginal wall the size of a walnut. This was extirpated, and examination proved it to be a spindle-cell sarcoma. The patient convalesced well, although in poor condition at the time of the operation. Four years afterwards there was no recurrence.

Steinthal divides the disease into two varieties, the polypoid and the diffuse. The former more common in children, and usually situated in the anterior vaginal wall. The latter more common in adults, and found in any portion of the vaginal canal. In adults, when secondary to sarcoma of the uterus, usually first noticed as knobbed polypoid outgrowths in the vaginal vault.

Symptoms. — In children pain and tumor. In adults vaginal discharge and slight hemorrhage from surface of the growth.

Diagnosis made by microscopic examination.

Delay makes prognosis serious.

Treatment early and radical removal of the growth.

Kelly reports two cases where permanent recovery followed removal.

CASE OF SARCOMA OF THE UTERUS.[1]

BY F. H. DAVENPORT, M.D., BOSTON.

THE case I am about to report is interesting not only on account of the ultimate diagnosis, namely, sarcoma, but also for the preceding history, which covers a period of nearly five years. The patient was a married woman who had had one child, and was between forty and forty-five years of age when I first saw her, October 29, 1893. I was asked to see her by Dr. Lovett to operate for the removal of a fibroid polypus. She had had the usual symptoms of irregular flowing and leucorrhea. I found a round polypus about the size of a billiard ball attached by a small pedicle to the uterus, and removed it by twisting and severing the pedicle with scissors. She made a good recovery.

I next saw her in June, 1894, and found on bimanual examination what I supposed to be an enlarged and irregular uterus, the seat of multiple fibroid growths. The patient gave a history of six weeks' constant flowing, which, however, had ceased before she came to me. I advised doing nothing at the time, but in July she consulted her physician at her summer home, who found another polypus extruded from the os uteri. That was removed at St. Margaret's on July 11th. In October of the same year she began to have an increased flow and watery discharge between times, and in December a third growth similar in character to the previous ones was discovered and removed. These growths were to my eye typical fibroid polypi, and with the uterus presumably the seat of multiple fibroids, their gradual development and extrusion was explained. The growth in the pelvis was slowly enlarging. The question of some more radical operation was spoken of at this time, but family considerations made it extremely unwise then, and as the patient's general health continued good it was postponed. Nothing new developed until November 26, 1895, nearly a year, when the fourth polypus was removed. This was done at a time when there had been and still was considerable hemorrhage, and the operation was followed by a decided flow, which was checked by packing the uterus. In fact it was a peculiarity of all these operations that they were accompanied by more flowing than is usually the case.

April 21, 1896, five months after the last polypus, another was discovered. There had been a rapid increase in the size of the tumor since the last operation, so that it reached nearly to the umbilicus, and enlarged the abdomen considerably. It was still thought to be a fibroid. The operation was as usual, and the first day or two of the convalesence uneventful. On the morning of the third day the patient was found to be in intense pain in the abdomen, coming on in paroxyms, alternating with collapse, weak pulse, vomiting and suppression of urine. Under stimulation she improved, but was in a critical condition for twenty-four hours. On examining the abdomen at this time it was found that the tumor had disappeared and the abdomen was flat. Of course the explanation was a spontaneous rupture of a cyst, and the collapsed condition was due to the flooding of the peritoneum with the cyst contents and its efforts to absorb it. I regret that the exact notes of the case at this time cannot be obtained, as the condition was a very unusual and interesting one. Perhaps Dr. Lovett or Dr. Stone, both of whom saw her at the time, can give fuller details.

An examination of the specimen removed at this time by Dr. Curry, of the City Hospital, showed it to be a submucous fibroid which had undergone myxomatous degeneration, portions of which were necrotic, and into which there had been much hemorrhage.

The collapse of the tumor disproved the diagnosis of a fibroid, and put a new aspect on the case. I hoped that it was one of those thin-walled cysts of the broad ligaments which rupture easily and do not refill. Unfortunately that did not prove to be the case, for after some months the tumor could be again felt, and grew so rapidly that by November of that year it was deemed best to operate for its removal.

A laparotomy was performed on November 30th, and the following condition of things found: The uterus

[1] Read before the Obstetrical Society of Boston, February 21, 1899

was only slightly enlarged, and there were no fibroids in its substance as far as could be made out. Certainly none were visible on the external surface. On the left side there was an ovarian cyst about the size of a cocoanut, closely adherent to the uterus, and with a broad attachment to the broad ligament. This was slowly detached, the stump both of the broad ligament and along the side of the uterus being ligated with interrupted silk sutures. A smaller tumor of the same kind was found on the right side and was also removed. The question of removing the uterus was discussed, but as there was no apparent tumor, and the operation had already lasted over an hour, it was thought best to leave it. I was the more ready to do this since I had had a number of cases where uterine hemorrhage was a prominent symptom of adherent cysts of the ovary, and I hoped by removing the tumors and bringing about the menopause to check both the flowing and the formation of the polypi.

The convalescence following the laparotomy was uneventful, and it was confidently hoped that the long series of gynecological events had come to an end. Such was not the case however. February 8, 1897, about two months after the last operation, another polypoid mass was discovered, and removed on February 19th.

Through the spring and early summer the patient's general condition was fairly good, though it could not be said to be first-rate. There was considerable discharge, which at times was bloody, and her strength did not return as was expected. In July she had an illness at her home in the country which, while associated with some flowing and discharge and pain, was not definitely attributable to any uterine condition. I saw her at the time, and found no reason in her local condition for interfering.

In October, 1897, she began to flow and also to have pain, which would come on usually at a certain time of day, attain a good deal of intensity, and last from one hour to two or three. This was situated in the lower abdomen, somewhat to the right side, about the location of the right ovary. Examination repeatedly made revealed nothing but a slightly enlarged uterus, with nothing to account for the pain. There was considerable discharge, both blood and small grayish or reddish masses, which were twice examined by Dr. Whitney and pronounced merely blood clot, without any evidence of tissue. At this time she began to take morphia in very small doses, one-twelfth often sufficing to relieve the pain completely.

Although it seemed probable that some operation would be eventually necessary, yet in the absence of any direct evidence of a malignant growth there were certain very strong reasons involving family complications against any operation which might have a fatal termination. Through the winter of 1897 and 1898 her condition varied within moderately fixed limits. At times there was discharge and some flow, at others she was practically free. The pain varied greatly, at times interfering only slightly with her usual occupations, but sometimes so intense as to sap her strength and confine her to the bed or house for some days. She lost flesh, became sallow, and her nervous system, which was naturally very strong, showed the effect of the prolonged strain.

By the middle of April, 1898, it was thought best to explore the interior of the uterus more thoroughly, and a curetting was done on the 13th, which resulted in the removal of a mass of tissue which Dr. Whitney described as follows: The mass from Mrs. X consisted of a fragmentary, soft polypoid, necrotic and hemorrhagic tumor of considerable size. Microscopical examination showed a more or less homogeneous mass of small round cells, which were vascularized by relatively large thin-walled blood vessels with extensive hemorrhage and degeneration of the cells. The cells were mononucleated, rather elongated and irregular, and were of the type of connective-tissue cells. There is no evidence of any epithelial growth, and from the history taken in connection with the microscopic examination the diagnosis of a small round-cell sarcoma is justified.

This diagnosis rendered an operation necessary, so on May 5, 1898, at St. Margaret's, a hysterectomy was performed. The operation was a difficult one. It was begun by the vagina, the uterus being first curetted and packed. The vaginal mucous membrane at its junction with the cervix was then divided with the Paquelin cautery and an attempt made to tie or clamp the broad ligaments. Owing to adhesions and thickenings due to the double oöphorectomy previously done, this was found to be impossible, so the abdomen was opened, and the operation completed by that route. It was a long and tedious operation, but the patient stood it very well.

The convalescence was marked by two unusual events. On the third or fourth day the abdominal incision broke down and discharged a large quantity of foul-smelling pus. The abscess had burrowed between the layers of the abdominal wall, but did not, as far as I could make out by careful probing, communicate with the peritoneal cavity. For days there was considerable difficulty with nourishment, the patient vomiting frequently, and the bowels moving irregularly. She had considerable pain and required some morphine for its relief.

On May 15th, ten days after the operation, the evening temperature was 101°. The patient had had considerable pain all day, but the bowels had moved twice, and she had taken a fair amount of nourishment. On the morning of the 16th she vomited, appeared listless and indifferent to her surroundings, and disinclined to talk. The temperature had dropped to 98°. Throughout the day it continued to fall, and at 7.30 in the evening reached its lowest point, 95.08°. The pulse grew more rapid, and ranged from 110 to 120. She was given champagne in small quantities, enemas of salt solution, with brandy, brandy and ice by the mouth, strychnine, one-sixtieth grain, several times. She was not able to take any nourishment. Urine was passed at intervals, but the whole amount for twenty-four hours was small. The bowels moved by enema. Her general appearance was bad, and at my late evening visit I felt there was considerable doubt if she would live until morning. The temperature began to rise in the night, and the next morning was 99°, rising to a little over 100° that night and then dropping slowly day by day until in a week it was practically normal. With the reaction the pulse rose in frequency, reaching 135 on the evening of the 17th. Dr. Lovett saw her with me in this attack, and we felt we could eliminate septic peritonitis, or in fact any septic process, and I must confess I am to this day puzzled as to what caused this sudden change.

The convalescence was now rapid, the abdominal wound closed, and the patient went home at the end of four weeks. I have examined her within a week and

her condition is one of apparent perfect health now, nine months after the operation.

Dr. Whitney reported on the uterus as follows:

The preliminary examination of the tumor of the uterus from Mrs. X shows it to be a myxosarcoma which has started in the fundus, thus confirming the diagnosis made earlier from the scrapings.

SARCOMA OF THE UTERUS.[1]

BY WILLIAM F. WHITNEY, M.D., BOSTON.

SARCOMA of the uterus has been recognized for a long time though comparatively a rare affection. Geisler computed that it occurred in 1.2 per cent. of uterine tumors, and its relations to cancer and fibromyoma were in the proportion of 1 to 50 of the former and 1 to 36 of the latter. Without imposing too much upon your patience, I can only give what may be regarded as a short *résumé* of the results of observations upon this disease.

In the first place comes its clinical course and prognosis, and in the second its anatomical aspects.

In studying its history from the recorded cases we are met with the obstacle that they are rarely finished. Thus while the earlier history is fairly well given and the operative procedures for relief, the final outcome is often uncertain. So that whether treatment will prolong life and mitigate suffering must be for the present and future to decide, rather than the past, with its death list from sepsis.

In an analysis of 81 cases in which the age was given, there were found 12 before thirty years of age, and 70 between thirty and sixty-one years (the oldest), or dividing them at forty-five years (the climacteric), it was found that 26 occurred before and 45 after that period.

Or to put it in a way to be more easily remembered, it may be said that sarcoma of the uterus rarely occurs after sixty years of age, and that it occurs six times as often in the last half of that period as in the first half, and that the greater number occurs between the age of thirty-five and fifty-five years.

In regard to duration the analysis is rather more vague. But dating from the first appearance of symptoms till the end of the time of the published record of 57 cases, it was found that in 18 it had lasted two years, in 19 from two to six years, and in 22 under two years.

In dividing these up by decades it appears that a larger number of the longer cases falls between thirty-five and forty-five. This is perhaps natural, as during this period the vital forces are strongest and best capable of resisting the wasting effects of the disease.

The most prominent symptom is hemorrhage, being absent in only one case in which the symptoms were especially mentioned. Pain is often present.

Of the objective symptoms, enlargement of the uterus is very constant, with a tumor sometimes presenting at the os, or within the vagina, as a rule with a smooth surface, sometimes lobulated and not deeply ulcerated.

Death usually occurs from anemia and debility; metastases being rare, and when present often found in the lungs.

The differential diagnosis between this and cancer, or fibromyoma, will depend, in the greater number of cases, upon a histological examination. The etiology is as obscure, and as yet nothing which can even be regarded as a predisposing cause has been suggested. Age as a factor differs from that of sarcomas elsewhere, as we have seen that it occurs oftener after forty than before.

With this brief summary the clinical aspect of the disease can be left.

Upon the anatomical and histological characteristics we are much better informed, and numerous interesting facts have been brought out. Sarcomas are found starting from the fundus or the cervix, the latter presenting some peculiarities that have placed them in a class by themselves. Those of the fundus are subdivided by their place of origin, whether in the mucosa or in the wall proper. And to these is added a class which starts from the decidua or villi of the chorion, about which at present there is an active controversy. But this will be left out of consideration as it would take too much time.

The richly cellular tissue lying between the uterine glands needs but little change in the energy of its growth and the shape of its cells to become a sarcoma, and it is only to be wondered at that it does not occur more frequently. In its gross appearance it is a smooth, more or less lobulated, often polypoid growth, circumscribed or extending more or less completely over the entire endometrium. The glands may atrophy or keep pace with the development of the new growth, either preserving their typical form or becoming solid strings; in the latter case the variety of carcino-sarcoma is produced. Later the uterine wall may become involved and invaded, and a great development of blood-vessels take place with extensive hemorrhage. The case which Dr. Davenport has reported would illustrate a round-cell sarcoma of endometrial origin.

With the elongation of the cells the spindle-cell type is produced, associated, in a few cases, with multinuclear or giant cells. Those starting around the sheath of the blood-vessels (perithelioma), as well as those with a hyaline degeneration of the vascular walls (cylindroma), have also been reported, and in short all the varieties which the ingenuity of the histologist has been able to devise have been found here.

In the wall of the uterus the tissue between the muscular fibres may be the place of origin, or it may arise from the degeneration of a fibromyoma. For a long time such a change was considered probable from the appearances to the eye, but the microscopic proof of this was furnished by two independent observers, Williams[2] and Pick,[3] at the same time, who have shown the direct metaplasia of the muscular fibre into sarcomatous tissue, and Van Kahlden,[4] who has described the same change of the fibrous tissue.

To the eye the sarcoma of the wall appears as soft, homogeneous, pale reddish-gray nodules which may grow into the cavity of the uterus as polypoid masses, and in their advanced stages their point of origin is not always easy to make out and often requires careful study. The peculiar form which occurs in the cervix has been well presented by Pernice[5] and Pfannenstiel,[6] and the latter has collected twelve cases. He designates it as a "botryoidal (berry-like) sarcoma of the

cervix." It occurs chiefly at puberty or towards the climacteric, and in all the cases so far described has been fatal. It appears usually as a polyp, in some cases so deeply lobulated as to look like a mass of red berries (from whence its name).

In several cases the orginal growth has been removed, and the microscopic examination has shown the character of a simple mucous polyp; later it has recurred and cells of varying size and shape have been found. Usually the later structure is that of an edematous fibroma, to which in a few cases a second tissue cartilage or striped muscular fibre of an embryonic type has been joined.

It has been suggested that as yet a radical operation (hysterectomy) has not been done in any of these cases, from the apparently benign character of the primary growth, and that the prognosis should not be worse than in other sarcomas, since metastases are infrequent.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

Meeting of February 21, 1899, the President, Dr. Alfred Worcester, in the chair.

Dr. F. H. Davenport read a paper entitled

A CASE OF SARCOMA OF THE UTERUS.[1]

Dr. E. H. Mackay read a paper entitled

A CASE OF MYXOSARCOMA OF THE UTERUS AND VAGINA, FROM THE SERVICE OF DR. J. G. BLAKE AT THE BOSTON CITY HOSPITAL.[2]

Dr. R. G. Wadsworth read a paper by Dr. S. J. Mixter entitled

A CASE OF SARCOMA OF THE UTERUS.[3]

Dr. W. F. Whitney opened the discussion.[4]

Dr. J. G. Blake said that his case had been very interesting and to him a unique one. The vagina was filled with a large fungous-looking mass, which on examination by the pathologist was said to be a spindle-celled sarcoma.

Dr. Whitney said that Dr. Davenport's case was probably of endometrial origin. He regretted that the changes in Dr. Mixter's case could not be followed; also that an autopsy could not be obtained.

Dr. Pearse said that Dr. Blake's case started from the uterus and involved the vagina. The growth was a giant-cell spindle sarcoma, which is very rare, Williams finding giant cells in only 12 out of 100 cases.

Dr. Engelmann said that he had always looked upon the growth as developing subserous or submucous like the fibromata, instead of, as Dr. Whitney said, from the muscular layer. He always advised a radical operation after one thorough curetting. He thought he had seen cystosarcomatous degeneration after treatment; he has never seen sarcoma developed in the vagina or cervix.

Dr. Washburn had seen one inoperable case develop in the fundus; the patient lived six months and died of exhaustion.

Dr. Whitney said while the development of sarcoma from the muscular elements of the uterus was not common, yet he believed such change does take place. It was often very difficult to decide whether the growth was from the muscle or the submucous tissue. The cases of Williams, Pick and others seemed to support the theory that there is a direct transformation of the unstriped muscular fibres into sarcomatous tissue. These cases should have an early radical operation, and the prognosis would be certainly more favorable than in carcinoma, as they do not invade other tissues or form metastases as early or rapidly as in that disease.

Dr. Davenport said delay in the final radical operation in his case was because of several curettings for examination, etc.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held at the Academy of Medicine, in New York City, May 9, 10 and 11, 1899.

(Concluded from No. 8, p. 199.)

Dr. Otis read a paper by Dr. R. H. Babcock, of Chicago, entitled:

ALTITUDE AND HEART DISEASE, WITH REPORT OF CASES.

Dr. Henry Sewall: All discussion as to the effects of altitude on heart disease is based on theories of the mechanics of circulation, of which we know very little. My colleague, Dr. W. H. Bergtold, tells me that his results of study of the blood in Denver show a very extraordinary increase of specific gravity. It is stated on good authority that preceding a loss of compensation in heart disease we have a sudden diminution in the specific gravity of the blood. For a long time I have given particular attention to conditions of circulation in people living in Colorado, and I am convinced that in most normal hearts there is an overtaxing of the right side which persists for some days or weeks after arrival in that region. The proofs of this lie in observations upon the reduplication of the heart sounds. The observations I have made from a clinical standpoint agree quite closely with those made by Dr. Babcock. After a little while, the signs which indicate this overburdening of the right heart disappear in those cases which do well, but not in those cases which do badly. Mechanically, the heart can stand more insult than any other organ in the body. This has been shown by the experiments of physiologists on mammalian hearts. This overloading of the right side of the heart which is evidenced during the early stages of a sojourn in high altitudes is easily explained by the increased aspiration of blood into the thorax; compensation occurs later in the increased capacity of the lungs. After the right heart becomes stronger and the pulmonary capacity is increased the circulation will go on quite well.

I have had under observation for some months a patient with marked mitral stenosis who came to me from Chicago, where she had been under the careful observation of Dr. Babcock. When I saw her about six months ago during her last trip in Colorado, I questioned her carefully as to the effect of various altitudes upon her condition. She said she could stand Colorado Springs, with its altitude of 6,100 feet, with

[1] See page 214 of the Journal.
[2] See page 213 of the Journal.
[3] See page 212 of the Journal.
[4] See page 216 of the Journal.

only fair comfort; in Denver, 5,280 feet, she was just as comfortable as in Chicago, and better than in Los Angeles; but at Cripple Creek, with its altitude of 9,300 feet, she at once began to feel uncomfortable, and at the end of a week broke down completely. Two months ago I saw the patient through an attack which had come upon her in Cripple Creek. She soon after returned to her normal condition.

DR. CHARLES E. QUIMBY, of New York: For seven years I have been treating all forms of valvular and mural diseases of the left heart, with the exception of mitral stenosis, by pneumatic differentiation. There is no other therapeutic measure whose action is so definite or constant. While it is true that liquids are incompressible, nevertheless in the treatment of cardiac disease we must recognize a force that is developed by blood compression.

DR. BABCOCK: I am very sorry that I did not hear more from our Colorado contingent, for I began to be very shaky about the correctness of my theory. Practical experience is worth more than theory, and these men have all had experience with cardiac patients which might entirely upset the theory that the rapidity of the circulation was the cause of the disturbance of the heart in certain cases. Particularly was I overwhelmed last night when Dr. Sewall informed me that one of my patients with pronounced mitral stenosis was walking about Denver in comparative comfort. Nevertheless, I think that as a rule the principle can be laid down that mitral or aortic stenosis should be regarded as contraindications to a residence in high climates, also when there are complications such as pleuritic adhesions. One individual with a certain degree of mitral stenosis can endure the altitude of Denver while another with a similar lesion cannot endure a much lower altitude, and it is hard for us to explain this. The explanation will probably be found in some change in the myocardium, perhaps a degeneration, which, when co-existing with valvular disease, will determine whether or not patients can sojourn in certain altitudes. My paper was simply offered in the way of a suggestion, and in the hope that it would stimulate the members of this Association to report more cases of this kind, and to lead them to realize that the mere existence of cardiac disease does not, *per se*, contraindicate a sojourn in high climates.

DR. S. EDWIN SOLLY, of Colorado Springs, read a paper on

RECENT INQUIRIES CONCERNING BLOOD CHANGES INDUCED BY ALTITUDE.

All admit that there is a real or apparent increase in the number of red blood cells within a day after ascent to a high altitude; the hemoglobin and specific gravity of the blood also increase; on returning to a lower altitude these factors decrease, but a secondary rise follows. Experiments upon animals in bell-jars proved that blood taken from the aorta and liver showed an increase of from 20 per cent. to 50 per cent. in the number of red cells as the pressure increased. A short time after the animals were removed there was a decrease and then a rise which persisted so long as the animals were under observation. Anæmic children were observed to have an increase after being sent to the mountains, and a persistent increase after their return. The number of red cells has been noted under these experimental conditions to be the same in blood taken from aorta and liver as from peripheral vessels.

Dr. Solly holds that the increase of red cells on ascending to an altitude is real and not apparent, and he made a request that physicians would make careful records of the blood before sending patients to Colorado. It was urged that the Association take the matter in hand and appoint a special committee to conduct such an investigation.

DR. E. O. OTIS: When Dr. Solly read his exceedingly interesting paper last year before the Philadelphia County Medical Society, I expressed myself then as not convinced from the proof which he adduced that the polycythemia to which he referred was a genuine one and not limited to the peripheral vessels. I still do not feel quite sure that this is a true polycythemia. Is it a fact that the whole mass of blood is increased, and are the experiments which have been made thus far conclusive? We have, it is true, the experiments of Egger, who found this polycythemia in the blood taken from the deeper vessels, and we have these further experiments as narrated by Dr. Solly. Granting the fact that there is an actual increase of red blood corpuscles in the whole mass of the blood, how do you explain the fact that there is a rapid destruction of them on returning to the sea-level without, apparently, any more signs of general destruction than we know does occur? Why is such a return to the level not accompanied by the symptoms which occur when a similar destruction is the result of ordinary disease, as in icterus and hemoglobinuria?

Dr. A. JACOBI: There is one point that struck me, namely, the disproportion between the increase of red blood cells and the hemoglobin. This, I think, is a very common occurrence, and it should not be attributed to the effects of altitude. We see it continually in convalescents. Yesterday I examined the blood of a boy of seven years who, six weeks ago, after having been anemic all winter, had three and one-half millions of red cells and from seven to eight thousand leucocytes, and 60 per cent. of hemoglobin. His breathing was shallow, but he was fairly comfortable as long as he did not exert himself. Yesterday he had four and one-half millions of red cells, and fifteen thousand leucocytes, a proportion of one to three hundred, and only 56 per cent. of hemoglobin. The disproportion sets in during slow convalescence. I have frequently seen the same thing before, and certainly the condition cannot be attributed to the effect of altitude alone.

DR. JUDSON DALAND: Those men who have been working with blood most confess that although their methods are the most accurate in existence considerable variation in the results exists, which to some extent vitiates their value. For example, in examining the blood of twenty-five persons, all presumably in good health, with the instrument of Thoma-Zeiss, the variations in the count of red corpuscles ranged from two to five hundred thousand, the count being made from the same drop of blood by two different observers. In making our calculations we count sixty-four squares, and the number of corpuscles actually counted in proportion to the whole number contained in the cubic millimetre is comparatively few, so that a slight error by multiplication amounts to considerable. We observe also in using the hematokrit, that the question of the size of the corpuscle comes in.

Each corpuscle occupies a certain amount of space, and this again causes inaccuracy. In using Fleishel's hemometer, the colored dilution of the blood compared with the colored wedge of the glass may cause mistakes. A variation of five per cent. or less I consider legitimate. Another point is that the light in the hemometer should be properly regulated. Very frequently, if the light is strong, we are unable to make a comparison. Still another point is to reduce the area which is under observation, cutting down a large area to a narrow slit, thus minimizing the chance of error, and what we call focusing the eye of the observer upon the wedge shaped piece of glass deserves consideration, as if you place the eye directly over the narrow slit your count is more apt to be correct.

Whether there is or is not an actual increase in the number of red blood cells per cubic millimetre resulting from high altitude I do not know, but it seems to me that it is fairly safe to conclude that there is a blood regeneration. The general effect of the climate in high altitudes is usually beneficial; there is an improvement in the general health, and the blood-making process is a part of that. We may therefore reason from that point of view. In those cases where a diminished quantity of air enters the chest there is a corresponding diminution in the amount of hemoglobin and the number of red blood cells. The red blood corpuscle is more or less the index of the amount of oxygen required by the body, and we can have a very rapid increase in the number of red blood cells without a corresponding increase of hemoglobin. Where we have large volumes of air enter and leave the chest there is a greater demand on the part of the body for oxygen, and nature's response to that would be the production of a larger amount of hemoglobin and probably of hemoglobin carriers.

DR. B. P. ANDERSON, of Colorado Springs, read a paper on

INTERMEDIATE ALTITUDE FOR THE CONSUMPTIVE.

He said: My experience has been that in some of this class of cases benefit is received by a change to an intermediate altitude, and for the past several years I have urged such cases to seek temporarily an altitude of from 3,000 to 4,000 feet above the sea-level, and, if benefited, to remain until all active symptoms disappear. Following this advice, the rule has been that such cases were enabled to return to the higher altitude of Colorado Springs, and upon the second trial improvement continued. Experience has again taught the pertinent fact that the class of cases coming under observation which do not improve or show evidence of a subsidence of active symptoms after a residence of five or six weeks will not be benefited by longer stay, but, on the contrary, will continue to lose ground, and should be ordered a change at once. In advocating the change to a lower or intermediate climate I would be understood as meaning those cases which we term curable, or at least in which a favorable prognosis has been given. In the selection of the most favorable climate for such cases I was largely aided by having my attention called some eight years since to the Mesilla Valley, in New Mexico — a valley situated about forty-five miles northwest of El Paso, Texas. Invalid patients coming to Colorado for the cooler summer months, after having spent the winter in this valley, were the first to attract my attention. Their enthusiasm as to dryness, sunshine, the greater number of days one could remain in the open air, etc., did not impress me so much — all of which advantages we have here in Colorado — as did the fact of their improvement, which could only be attributed to the advantage of altitude, which averages from 3,500 to 3,800 feet, combining with its lower altitude the important essential of a maximum amount of sunshine and dry air. Commencing with the fall and winter of 1892, I have regularly advised those patients who for the most part did not progress favorably in Colorado to seek this climate. Since 1892 I have a record of somewhat more than 200 cases who spent the winter months in this climate. My record embraces many cases in the various stages of advancement of disease, and many were complicated with laryngeal tuberculosis. The subsequent history of these cases shows that a large majority, or 70 per cent., improved, and are still living.

DR. LEONARD WEBER, of New York: I think it is safe to say, after listening to this paper, that the medical profession both in this country and on the other side of the Atlantic are all agreed that what the consumptive wants is pure air, and I think the time is approaching when high altitude will not be considered of such paramount importance in this connection as it was some years ago. This change of opinion has been brought about by the fact that good results in the treatment of phthisis are being obtained in sanitaria situated at altitudes of only 300 feet or even less above the sea-level.

It has always been my practice in the treatment of incipient pulmonary tuberculosis, particularly when the disease is unilateral, to send such patients — providing there be no contraindications in the way of heart or kidney trouble — either to Davos, in Switzerland, or to the Rocky Mountains, or to Southern Texas or Colorado, because I have found that in those regions they were more apt than elsewhere to recover from their disease, or at least have progress stopped.

In a second class of patients, where the disease is more advanced in one lung, and I suspect beginning infiltration in the other, together with considerable fever and an irritating cough, my experience has taught me that they do better at moderate altitudes, say about 3,000 feet above the sea-level, in regions such as the author of the paper mentioned. Of course, we all know of even advanced cases, with hemoptysis, that improved at very high altitudes, but I know of other instances where such patients when sent to Colorado did not do well at all and had to return to lower levels.

DR. NEWTON, of Montclair: In connection with this subject of sending our patients away to various places where they may get the benefit of the altitude, we should not lose sight of the question of proper food to suit an impaired or feeble digestion. I have seen men out on the frontier who could eat almost anything and thrive on it, but when we are dealing with patients who suffer from the indigestion so common in pulmonary tuberculosis, they had better be kept at home unless we are convinced that they can obtain proper food elsewhere. We cannot fight tuberculosis with poor food. The digestion should always be kept well in sight — much more so than it usually is. A cheerful disposition and good digestion will help a man to recover from pulmonary tuberculosis, at home or elsewhere, while a man who is easily discouraged and who suffers from poor digestion will be handicapped in the best of climates.

Dr. James B. Walker, of Philadelphia, read a paper on

CLIMATE IN RELATION TO RENAL DISEASE.

He considered the influence of variability of temperature and dampness, particularly of the soil, on persons afflicted with renal diseases. In winter, when patients were not inclined to do so well as in summer, he was in the habit of sending them to Lakewood or Atlantic City.

Dr. Coleman, of Augusta, Georgia, testified to the comparative infrequency of renal disease in the South. The negroes have it more commonly than the whites, owing to poorer clothing and less hygienic surroundings.

Dr. Judson Daland, of Philadelphia: I was interested in listening to Dr. Walker's paper on the subject of the effect of climate together with the state of dryness of the air and soil on renal disease, and was glad to hear food mentioned in connection with the subject. Probably this food question comes in a little stronger than one might infer from the paper. That a distinction should be made between a winter diet and a summer diet is perfectly clear to us all, and perhaps in the very climate to which he referred the dietetic reactions are shown the soonest. Another point is the quantity of food that is required in different climates. In a warm climate the food required would probably be from fifteen to twenty per cent. less than in a cold climate, and in addition to that you get the benefit of freer action of the skin, and also the action of water, which is taken in larger quantities in such climates.

Dr. Newton: I wish to add my testimony to the value of such a climate as that of Northern Texas in kidney troubles. I do not remember having seen more than one case of Bright's disease during my four years' residence at Ft. Elliott, which is located in what is known as the Panhandle district of Texas. There the climate is very dry and the people are so dry that they drink all they can get, including a great deal of whiskey.

The rarity of Bright's disease in Texas is referred to in the writings of Dr. H. C. Wood. The subject is a very important one, and is certainly worthy of further investigation.

Dr. Phillips, of Washington: The Doctor attributes the benefit derived by nephritic patients who are sent to Lakewood and Atlantic City to the dryness of the soil and atmosphere. The soil of Atlantic City may be dry, but the air there is much damper than it is, for example, at Philadelphia. To explain the beneficial effects derived there by patients, we must look to something besides moisture. Atlantic City has a much more equable temperature than Philadelphia, the diurnal variations being much less; the temperature does not go up so high during the day nor fall so low at night, and for that reason the patient is better able to protect himself with proper clothing. I think the benefit derived by patients suffering from renal disease in certain regions, at least along the Atlantic seacoast, is due more to the temperature than to the moisture. In very dry climates, where perspiration is free and the skin does most of the work, the kidneys are a less important factor.

Dr. S. A. Fisk, of Denver, stated that he rarely met with a case of Bright's disease in the Rocky Mountain region, and stated his belief that simple albuminuria is not a contraindication for sending a patient to Colorado; on the contrary he finds that such patients do very well. He cited a case under his observation ten or twelve years that corroborated his view.

Dr. Henry Sewall, of Denver, laid stress on the variability of climate, the constant changes producing irritation, especially when the organs are diseased. In a moist climate conduction is more rapid, chilling is more intense, and the congestions of the internal organs more severe. Dr. Sewall claimed that, because of the altitude, radiation and evaporation are rapid and the temperature equable, therefore sudden chilling of the body surface and internal congestion are less liable to occur.

Dr. L. D. Bulkley, of New York, stated that thirty years ago, while an interne at the New York Hospital, he had albuminuria. He left the hospital, lived on a milk diet, and was told that he could not live very long in New York. He thereupon decided to go to Brazil, but was detained at home. During these thirty years he has had several severe attacks of albuminuria, and one of his sharpest attacks occurred while he was travelling in the Yellowstone Park, where the air is certainly very dry.

While Dr. Bulkley does not entirely accept the statements made regarding the value of climate in renal disease, he said that the condition of the atmosphere has a decided influence upon the frequency of micturition. On certain days the urine will diminish to a few ounces, while on other days urination will be very free. As regards treatment, he lays the greatest stress on the diet and the care of the skin, referring not so much to bathing as to the constant application of woolen garments to the skin, both night and day. This he has practised for years. In addition to this, he drinks a quart of milk daily on an empty stomach. This causes a certain amount of diuresis.

Dr. Bulkley gave these details to show that it is possible for a person with marked albuminuria to live in New York City for at least thirty years, providing he takes proper care of himself.

Dr. N. S. Davis, Jr.: A few days ago I was looking over Dr. Stillman's book, "The Life Insurance Examiner Searching for Statistics," and I happened on figures relating to this subject, the geographical distribution of renal affections. In that book there is a table giving the mortality derived from 5,000 fatalities among insured cases in each of the following groups of States: In the New England States and New York the mortality from renal affections was 3.5 per cent.; in Michigan, Wisconsin, Minnesota and Nebraska, 1.4 per cent.; in New Jersey and Pennsylvania, 3.1 per cent.; in Ohio, Indiana, Illinois, Iowa and Kansas, 1.9 per cent.; in Delaware, Maryland, the District of Columbia, Virginia, Kentucky and Missouri, 2.1 per cent.; in the Southern States, 2.4 per cent.; in Washington, Oregon, California, Utah, Dakota and New Mexico, 2.6 per cent.

It would appear from these statistics that the lowest mortality from renal affections occurred in the northern part of the Mississippi valley, while the highest was in the four Western States, namely Washington, Oregon, California and New Mexico. The next highest mortality was in the Middle Atlantic States and New York.

Dr. Newton: I would venture to suggest that life insurance statistics in northern Texas are apt to

be misleading, as it is rare out there to find a man who has his life insured. The majority of these are invalids from other localities and their death-rate would be naturally high.

DR. CHARLES F. MCGAHAN, of Aiken, read a paper on

THE NEED OF MUNICIPAL CONTROL OF THE FUMIGATION OF APARTMENTS OCCUPIED BY TUBERCULOUS PATIENTS AT HEALTH RESORTS.

He said: I have seen apartments in which have been the worst cases of phthisis disinfected in the most superficial manner, and a few days later have been called to the same rooms to see a case showing only the first symptoms of phthisis. Many take apartments without consulting a physician for weeks or months. Landlords are ignorant as a rule of methods of disinfection, and simply make a farce of it. Every room offered for rent at a resort frequented by tuberculous patients should have a certificate attached to it stating it to have been thoroughly disinfected under the auspices of the board of health or sanitary inspector, and that it is, in the opinion of the board, perfectly healthful. Dr. McGahan advocated laws against the spitting nuisance.

DR. E. O. OTIS, of Boston, stated that in Boston the Board of Health is willing to disinfect any apartments which have been occupied by a consumptive, but this is not compulsory. Dr. Otis detailed the system adopted in Cannes, France. There the proprietor of a hotel or villa is notified by the attending physician that a room or apartment which has been occupied by a tuberculous patient, or in which one has died, must be disinfected or renovated before it can be again occupied. The proprietor takes this notification to the sanitary authorities; the disinfection is made by them, and they return the original card of notification to the physician, with a note on it that this has been done. In the mayor's office is a list of hotels and villas whose proprietors agree to conform to these suggestions. Physicians make use of this list and it is mutually advantageous.

DR. GUY HINSDALE: I appreciate very highly the importance of the suggestions contained in Dr. McGahan's paper, and I believe they would do much good if they could be brought to the attention of hotel-keepers in a manner that would appeal to the success of their establishments. The Pennsylvania Society for the Prevention of Tuberculosis has issued a tract on this subject which has been widely circulated, over 10,000 copies having been sent out. It is entitled, "How Hotel-keepers Can Assist in Preventing the Spread of Tuberculosis." We ought to decide upon a practical and efficient method of disinfecting an apartment which has been occupied by a tuberculous subject. Probably the best way is by the action of sunlight. In addition to this, or instead of it, some advise scrubbing with a strong corrosive-sublimate solution or the use of formaldehyde. A paper properly drawn up by this Association and widely circulated would do good.

DR. MCGAHAN: This subject is now being agitated in my home at Aiken, where some members of the Board of Health are in favor of adopting a system of fumigation, while others are not. Unless the fumigation is thorough it is practically useless. The apartments at the various hotels are successively occupied by different classes of patients, some of whom are careful about expectoration, while others are not. I do not think that we can rely upon the proprietors themselves to attend to the proper disinfection of their apartments. A regular system should be organized and carried out, and it seems to me that the health authorities are the proper persons to take hold of it.

(To be continued.)

Recent Literature.

Degeneracy: Its Causes, Signs and Results. By EUGENE S. TALBOT, M.D., D.D.S., etc. Pp. xvi, 372. With 120 illustrations. London: Walter Scott. 1898.

Of late years "degeneracy" has become a favorite phrase, and newspaper science and Nordau's sky-rocket book have done much to make it the fashion. It is a question, however, whether the foundations of this new "science" are quite so firmly established as some writers claim and whether, after all, it is not somewhat akin to the pseudo-sciences of physiognomy and phrenology. That there is a portion of truth in all the talk about "stigmata of degeneracy" is certain, but the importance of these stigmata is too often overrated, and many writers group among the stigmata every deviation from the normal, both physical and mental, whether congenital or acquired, so that everything, even symptoms of local disease of external and accidental origin, is regarded as significant of the degeneracy of the individual. That there is a class in every community which may fairly be regarded as degenerate is certain, and it is also true that in this class we find a much larger percentage of deviations from the normal type in their physical make-up than we do in presumably healthy individuals. It is, however, going too far to consider these deviations, which may occur with less frequency in the healthy, as proof or even as important indications of degeneracy in the individual. It is, furthermore, hardly fair to class the weaklings in the community who become defective on account of some acquired defect in early life with those who are defective from birth from hereditary causes, and to draw conclusions from the two classes combined. This, however, is the tendency of many of the writers on degeneracy, and the volume before us is not free from that error. It is, however, an interesting popular presentation of the subject of degeneracy. Much of it is, of course, a compilation, showing a diligent but not always discriminating study of many contributions to the subject. In the study of anomalies of the face and jaws, however, the author gives many interesting results of his own long and careful observation. The book is an interesting and valuable review of the subject, exaggerating, as is not unnatural, its importance.

Clinical Lectures on Neurasthenia. By THOMAS D. SAVILL, M.D. Pp. xv, 144. London: Henry G. Glaisher. 1899.

These lectures were delivered at the Welbeck Street Hospital for Diseases of the Nervous System as a part of the post-graduate course in 1897–1898. The author claims that the subject "is either not referred to at all or is very inadequately dealt with in the text-books in current use." If that were the case

they might be of some assistance to the practitioner and student, but in point of fact they are so far behind our present knowledge of neurasthenia, both as to symptomatology, pathology, prognosis and treatment, that we can see no reason for their publication.

A Treatise on Aphasia and other Speech Defects. By H. CHARLTON BASTIAN, M.A., M.D. (Lond.), F.R.S. Pp. viii, 366. With 31 illustrations. New York: D. Appleton & Co. 1898.

This volume, which includes the Lumleian Lectures delivered in 1897, is an exceedingly valuable contribution to this complicated and much discussed subject. The author's own researches in the subject are well known, and in the present volume these are supplemented by the reports of many other cases, making a total of one hundred and fourteen, and by a thorough review of the literature of the subject. The author's own views upon the vexed questions of the functions of speech are well known,— that the so-called motor centre is really a kinesthetic centre, that there is a writing centre distinct from the speech centre and that the proof of Broadbent's ideational centre is still lacking. These views are maintained with great skill and a strong array of evidence. Since the publication of the book the author's position in favor of a separate graphic centre, as opposed to the views of Dejerine, Miraillié, Collins and others, has received striking confirmation by the remarkable case of Gordinier. While somewhat less elementary and systematic than the work of Wyllie, and therefore less adapted for the beginner, the wealth of illustrative material and the philosophic judgment displayed will render it for a long time one of the standard treatises on the subject.

On the Relation of the Nervous System to Disease and Disorder in the Viscera. By ALEXANDER MORISON, M.D., F.R.C.P., etc. Pp. xiv, 132. With 39 illustrations. Edinburgh and London: Young J. Pentland. 1899.

This is a reprint of the Morison Lectures delivered before the Royal College of Physicians in Edinburgh in 1897 and 1898 by the grandson of the founder of the lectureship and published just a century after that founder graduated from the University of Edinburgh. The subject, although somewhat different from the usual theme of those lectures — the study of mental diseases — is one too much neglected and still obscure. The lecturer has summarized our present knowledge of the histology of the nerve supply of the viscera, with its physiology and pathology, and has added the results of his own study of the nerves of the uterus, the heart and the cerebral blood-vessels. The relations of the nervous system to disease in the viscera are still vague, but their importance is unquestioned, and these lectures afford many valuable hints in showing the need of further study and the limitations of our present knowledge.

IT is stated that the increase in the number of women students at German universities during the last few years has been remarkable. In 1896 there were only 177 at the ten leading universities, but at the beginning of the present year the number had risen to 414. Most of the women take courses in philology or philosophy. Only 16 have studied medicine, six theology, and six law in the last four years. — *Journal of the American Medical Association.*

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 31, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

EMERGENCY STATIONS.

WITH the recent closing of the Emergency Hospital for lack of funds, the important question is at once forced upon the City Government and the medical profession as to whether emergency stations shall be established under a different organization.

There are several points to be considered: First, are such hospitals needed in a large city? Secondly, if needed, how may they best be supplied? Thirdly, what are their limitations?

In answer to the first question we may unhesitatingly say that emergency stations are needed. As a city grows, the opportunities for accident are evidently proportionately increased. The distance to hospitals already established is often too great, even with the best possible ambulance service, to justify removal of a patient without some preliminary aid in the way, for example, of checking hemorrhage, or stimulation. It is possible in cases of hemorrhage and severe shock for a patient to reach a hospital in a moribund condition, who, at least, would have had a better chance for life had there been the possibility of intelligent treatment near at hand. It is just that small remaining amount of strength that needs to be utilized at such critical times and not exhausted by a more or less rough ambulance ride of perhaps several miles. Unquestionably, then, any well-regulated city needs emergency stations in number proportionate to its size, in order that no accident within the confines of the city may happen far from adequate surgical or medical aid. This much a city owes to its employees and citizens.

Granted, then, that such stations are needed, how may they best be supplied? In our opinion, they should be provided by a city as an integral part of its hospital organization. Boston, for example, boasts one of the most completely equipped and well-managed city hospitals in the country. Why should it not still further increase its range of usefulness by providing an adequate emergency service for that portion of the city where, in the judgment of those

competent to decide, such service is needed? It must, of course, always be borne in mind, that the hospitals already established provide an emergency service for large areas of the city in which they are located. An extension of this service, is, however, desirable, in the business portion, situated at a distance from the large hospitals and in a district where accidents are likely to occur. It appears that this has been the earnest wish of the Board of Trustees for many years. They have repeatedly petitioned those in authority for appropriations looking to a down-town relief station, to be under the direct control of the City Hospital. This has been persistently refused, and the city now finds itself, with the closing of the Emergency Hospital, which was a private institution, without facilities of any sort for the treatment of emergencies near the region at which accidents are likely to occur. This station must ultimately be supplied by city funds, if it is to be permanent — that seems self-evident. The advantages of having the whole system under one jurisdiction has recently been pointed out by Mr. Shuman, of the City Hospital Trustees, when he says that such a station should be under the management of the hospital department, in order that accident cases may have continued treatment under one method instead of being taken to one hospital for first treatment, and subsequently taken to another for continued treatment, thus subjecting patients to undue examinations, operations and dressings, and dividing the responsibility, and also lessening the chances of a perfect recovery.

In the third place, if such a station be established its limitations should be clearly recognized, and the idea of "emergency" and "accident" never for a moment lost sight of. This was embodied in a communication of a committee of the Visiting Medical Staff of the City Hospital in 1895. In this communication they said that they did not believe that such a station should be a hospital in the ordinary sense, but rather a station where a person suffering from accident, sudden sickness or other emergencies could receive immediate attention, and thence be transferred to the Boston City Hospital or other hospitals for further treatment, or to their homes. They said that they believed that such a station properly organized should have all the means and appliances for meeting readily any emergencies, large or small, that were liable to arise in the city of Boston, with the further implication that no other cases were to be treated. If such a limitation were adhered to it is evident that the number of beds could be reduced to a minimum, with an accompanying reduction of expense, and a most efficient service provided.

It is to be hoped that the efforts of the Trustees of the City Hospital may be at an early date successful, and that more definite action may soon be forthcoming leading to the establishment and maintenance of this much-needed adjunct of a well-organized medical charity.

THE YELLOW-FEVER QUESTION.

Controversy is, no doubt, one of the best aids to truth. The critical spirit which is born of disagreement tends to discover flaws in method or argument which a mere superficial acceptance of facts could evidently never accomplish. An instance of this effectual, if unpleasant, method of arriving at facts we have been observing for some time in the active discussion which has been going on between Professor Sanarelli, of Bologna, Italy, and Surgeon-General Sternberg and others, regarding the etiology of yellow fever. The details of the discussion are interesting, owing to their technical character, only to special students of bacteriological matters; the general results are, however, of the greatest significance and importance to us all.

Two papers have appeared in recent numbers of the *Medical News*, the first by Sanarelli, restating his position and conviction that his *bacillus icteroides* is the specific cause of yellow fever, and attacking with considerable energy Novy's recent work and also Sternberg's. The paper is controversial, and vigorously written, and whatever the ultimate merits of the question may be, states certain wholesome facts in perfectly definite fashion, ultimately replying to the critics in the following words:

"I (Sanarelli) am inclined to doubt if those who find it so easy to criticise are in a position to treat the bacteriological and pathogenetic questions of the infectious diseases with as much experience and authority, for these can only be acquired after many years of practical study at the bedside of the sick, in the autopsy-room and in the laboratory of comparative experimental pathology."

To this paper Sternberg replies in the succeeding number of the *Medical News*, defining his attitude toward the subject, and quoting from his recent publications. The paper is defensive throughout and closes with certain statements, some of which are as follows:

That some bacteriologists who claim to have found Sanarelli's bacillus have mistaken it for one of the varieties of the colon bacillus; that experiments made with Sanarelli's serum in high dilution give the Widal reaction with the bacillus of hog cholera; also, that serum from an animal immunized against hog cholera, in high dilutions, causes arrest of motion and typical agglomeration of Sanarelli's bacillus; also, that cultures of Sanarelli's bacillus fed to pigs cause the death of these animals, and that the typical lesions of hog cholera are found in their intestine; that blood serum of yellow-fever patients or of convalescents from this disease does not give a marked Widal reaction with Sanarelli's bacillus, although the blood of an animal immunized by the injection of cultures of this bacillus does give the specific reaction in high dilutions; that so far as I (Sternberg) am informed, the results obtained in the use of Sanarelli's antitoxic serum do not give support to his claim to have discovered the specific germ of yellow fever.

Finally, Sternberg writes:

"I would say it appears to me at the present time that, like the colon bacillus and bacillus *x*, the bacillus of Sanarelli is a pathogenic saprophyte which is present occasionally and accidentally in the blood and tissues of yellow-fever patients, and that its etiological relation to this disease has not been established."

In view of this very recent discussion and the forcible restatements of the two positions, it is of interest that the commission appointed by the Government to investigate Sanarelli's claims has handed in a report substantiating his conviction that the *bacillus icteroides* is the true cause of yellow fever. This commission, consisting of Surgeons Eugene Wasdin and H. D. Giddings, was appointed in November, 1897, and has since been prosecuting its investigation in the laboratory of the Marine-Hospital Service in Havana. The final report has just been published in the U. S. Public Health Reports, Vol. XIV, No. 33. The subjects of study were twenty-two cases of disease thought to be yellow fever by the native physicians in attendance, and in fourteen of which the commission concurred in the diagnosis. The conclusions derived from the investigation are:

"(1) That the micro-organism discovered by Prof. Giuseppe Sanarelli, of the University of Bologna, Italy, and by him named "bacillus icteroides," is the cause of yellow fever.

"(2) That yellow fever is naturally infectious to certain animals, the degree varying with the species; that in some rodents local infection is very quickly followed by blood infection; and that, while in dogs and rabbits there is no evidence of its subsequent invasion of the blood, monkeys react to the infection the same as man.

"(3) That infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the earlier manifestations of the disease.

"(4) That in many cases of the disease, probably a majority, the primary infection or colonization in the lungs is followed by a "secondary infection" or a secondary colonization of this organism in the blood of the patient. This secondary infection may be complicated by the coinstantaneous passage of other organisms into the blood, or this complication may arise during the last hours of life.

"(5) That there is no evidence to support the theory advanced by Professor Sanarelli that this disease is primarily a septicemia, inasmuch as cases do occur in which the bacillus icteroides cannot be found in the blood or organs in which it might be deposited therefrom.

"(6) That there exists no causal relationship between the bacillus *x* of Sternberg and this highly infectious disease, and that the bacillus *x* is frequently found in the intestinal content of normal animals and of man, as well as in the urine and the bronchial secretion.

"(7) That, so far as your commission is aware, the bacillus icteroides has never been found in any body other than one infected with yellow fever, and that whatever may be the cultural similarities between this and other micro-organisms, it is characterized by a specificity which is distinctive.

"(8) That the bacillus icteroides is very susceptible to the influences injurious to bacterial life; and that its ready control by the processes of disinfection, chemical and mechanical, is assured.

"(9) That the bacillus icteroides produces *in vitro*, as well as *in vita*, a toxin of the most marked potency; and that, from our present knowledge, there exists a reasonable possibility of the ultimate production of an antiserum more potent than that of Professor Sanarelli."

It is a matter of regret that more cases were not available for this study. While careful work in a few cases is infinitely more profitable than uncritical work on many, nevertheless, the importance of the question demands painstaking work on many cases by many competent observers, an outcome which we have no doubt will soon be forthcoming.

MEDICAL NOTES.

MARRIAGE OF THE SUBJECTS OF VENEREAL DISEASE FORBIDDEN. — A law recently passed by the Michigan Legislature, according to the *Medical Record*, forbids the marriage of any person suffering from gonorrhea or syphilis, and provides that any one so diseased who may marry shall be guilty of a felony punishable by a fine of not less than $500 or more than $1,000, or imprisonment in the penitentiary for a term not exceeding five years, or by both fine and imprisonment. A wife or husband may testify against her or his guilty spouse, and the privilege of medical secrecy is also abrogated in such cases.

THE CAUSE OF NIGHT TERRORS. — In a recent paper in the *British Medical Journal* Dr. E. Graham Little sums up the results of his observations as follows: Night terrors are in the great majority of cases caused by disorders productive of moderate but prolonged dyspnea. A preponderating number of cases are found in rheumatic subjects with early heart disease. A considerable proportion of cases are due to obstruction of nasal cavities and fauces. Digestive disturbances do not play the important part in causation that is often assigned to them. The evidence for their causal connection with epilepsy or allied neuroses is scanty. The attacks occur in the subconscious stage of early sleep, and are confined to young children under puberty.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 30, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease:

diphtheria 40, scarlet fever 22, measles 5, typhoid fever 40, small pox 2.

New Buildings for the Massachusetts General Hospital. — Work has been begun on a new operating building for the Massachusetts General Hospital, which is to contain an amphitheatre, smaller operating- and dressing-rooms, etc., and is to be constructed in every detail for facilitating aseptic work The operating theatre will seat one hundred and seventy-one persons. The building will be constructed of Chelmsford granite and brick. Two other buildings which are to be added to the hospital equipment consist of a domestic building, and an addition to the present nurses' dormitory.

New Cases of Small-Pox. — It is reported that two new cases of small-pox have been discovered in the Roxbury District. Neither case is of a severe type; one, a man, is practically well, and the other, a child, has been sent to Gallop's Island, The source of contagion is obscure.

Deaths of Centenarians. — Mrs. Mary Russell Bradford, believed to be the oldest person in New England, died at her home in Cambridge, August 27th, at the age of one hundred and six years, two months, eighteen days. She was born in Boston June 9, 1793, the daughter of Isaac and Mary Russell Winslow. She early married Charles Bradford, and up to about twenty years ago she lived in Boston. A year ago she was in excellent health, but failed rapidly during the last winter and spring. Mrs. Lucy Williams, who was believed to be the oldest woman in Connecticut, died at Uncasville last week, aged one hundred and three years.

A Correction. — The *Philadelphia Medical Journal*, in a New England note of the current issue, makes the following erroneous statement regarding the West End Nursery. "An interesting summer feature of the West End Nursery work is the branch service at Rainsford Island in Boston Harbor, with which is connected a training school for nursery maids. The form of prophylactic work promoted by this school appeals at once to anxious mothers, and the graduates are in great demand." The summer hospital at Rainsford Island has been discontinued.

NEW YORK.

The New Building of the Woman's Hospital. — Plans have now been completed for the new building of the Woman's Hospital of the State of New York, which the managers at first thought of erecting on a site further up-town, but afterwards decided to place on the present grounds of the institution, occupying the block between Park and Lexington Avenues and 49th and 50th Streets. The proposed new building will cost $400,000, of which amount considerably more than $300,000 has already been raised. Russell Sage, who is one of the Board of Governors of the Hospital, led off with a subscription of $50,000, and a like sum was also contributed by Mrs. Frederick Thompson, the treasurer.

The New York Water Supply. — Controller Coler has won the approval of the best citizens by his efforts to defeat what is known as the Ramapo Water Company job. If it should be deemed advisable to supplement the water supply now furnished by the Croton water-shed by the supply contemplated by the Ramapo Company, which includes an area of water-shed in Ulster and Greene, as well as Rockland and Orange Counties, on the west bank of the Hudson, he is of the opinion that the city itself should acquire the land required, rather than contract with any private company for the water. Under the circumstances, therefore, he has requested a corps of the city's engineers to make an investigation of the capabilities of the region referred to, and at the next session of the Legislature he proposes to secure for the city of New York, if possible, the right to go into any part of the State and acquire land that is decreed necessary for water-shed purposes. With this right of eminent domain secured, Mr. Coler states that, by extending the present Croton water-shed system to Ten Mile River, the supply can be greatly increased, and 100,000,000 gallons a day be obtained, at an expenditure of about $10,000,000. In the meanwhile, if the waste now taking place, not only through negligence on the part of the people, but from leakage from defective water-mains, could be checked or even reduced, the supply now at command would be ample for all the needs of the city for a considerable number of years to come.

Precautions Against Plague. — In a response to a communication addressed to them by Health Officer Doty, the two companies owning lines of steamers plying between Portugal and New York have promised not to bring over any passengers as long as bubonic plague exists in Portugal. Dr. Doty has announced that all vessels arriving from localities known to be infected will be treated as infected vessels, and he expresses his ability to successfully handle the disease should any cases of it be brought to the port of New York. The experiments carried on some time ago at the quarantine station laboratory on Swinburne Island, with cultures of plague germs obtained from Bombay and published in 1897, showed that the organism could be effectually destroyed by means of steam and formaldehyde. The disinfection by steam was performed in a steam chest, especially prepared, in which a vacuum was produced. Superheated steam was introduced within this chamber, which contained the infected material, inclosed in various wrappers, such as newspapers, rugs, blankets and sheets. The temperature of 170 degrees Fahrenheit was found sufficient to kill the germ if it was enclosed in a sheet of paper and envelope, while 250 degrees of heat, with an exposure of fifteen minutes, was certain destruction to germs wrapped in blankets or newspapers. The experiments with formaldehyde were most exhaustive, and various methods of employing this agent were tried, until the most efficient was secured. Since the successful termination of these tests, Dr. Doty states, the methods thus arrived at have been employed at

quarantine upon all vessels coming from forts in the far East where bubonic plague has been reported or its presence suspected.

Miscellany.

THE TONIC PROPERTIES OF SEA AIR.

CONSIDERABLE speculation has from time to time been made as to what causes the invigorating and tonic properties of a sea-breeze. Ozone is very commonly accepted as at any rate an important factor in this connection, since it is invariably present in air that has been in contact with sea-water, and especially agitated sea-water, and to a smaller extent in the air of the country, but it rarely occurs in the air of towns and crowded places. Ozone, however — and with it probably traces of hydrogen peroxide — is undoubtely formed by air skimming over the surface of fresh water, and hence the breezes coming over the lochs in Scotland and large lakes and rivers in other places become ozonized and bracing. The Briton has an instinctive fondness for procuring his change or spending his holiday down by the water side, be it sea, lake, or river, probably because he finds, though he does not know exactly why, that the air of water-side places does him more good than the air of the country, where there are trees and beauties of landscape but no large tract of water. The freshness of the early morning air is due most probably to the formation of dew on the previous night, the transition from the vaporous to the liquid state causing ozonization of the air with which the condensed watery particles come into intimate contact. This freshness disappears as the day wears on because of the readiness with which ozone is destroyed by organized and organic substances. The exhilarating effect of a sea-breeze may, however, be ascribed to other bodies which are foreign to inland air. Thus sea air contains a traceable amount of salt and iodides, attaining a maximum of 0.022 gramme per litre or about one and a half grains per gallon. These mineral ingredients derived from the sea doubtless accentuate the tonic action of sea air, and, further, it is probable that ozone interacting with chlorides and iodides would lead to traces of chlorine and iodine being present. Many persons describe the smell of strong sea air as iodous or chlorous, and it has even been said that the starch used in face-powders turns blue at the seaside on account of the iodine in the air forming blue iodide of starch. If that be so, the blue and haggard appearance characteristic of many faces exposed to a strongly salt-impregnated breeze would find an interesting, but perhaps embarrassing, explanation. — *Lancet.*

STREET NOISES.

THE *Medical Press and Circular* takes the following hopeful view of the noise question as regards London. We have not yet reached the point of improvement in America, but we may certainly hope for better things if London's Society has succeeded so well in its endeavors:

"The life of the average citizen is becoming more tolerable, so far as street noises are concerned, a happy state of things which is due not to the fact that he has become accustomed to such nuisances, but because the streets are quieter than they used to be. In a certain measure a good influence has been exerted in this direction by the London Society for the Suppression of Street Noises. Although only in the second year of its existence, the Society, as its report for the past year shows, has been steadily pressing forward an admirable campaign against the soul-disturbing costermongers and newsboys, who make the thoroughfares hideous with their yells and howls. Moreover, it is satisfactory to note that the Society has a well-designed programme in the pursuit of which its members intend to expend their best energies. For example, among their objects of reform are included the compulsory fixing of India-rubber tires on all vehicles, floors of the same material for milk-carts, the establishment of kiosks in place of the screeching newspaper boys. But even if all these reforms were successfully attained, many more noises would still be left to be dealt with. The bawling coal hawker, for instance, is an intolerable nuisance, and the irritating, expressionless, metallic clang of the barrel-organ should be banished altogether from the streets. Possibly, however, when the London Government Act comes into force, marked improvement will be noticed in regard to the prevalence of street noises, inasmuch as the new municipalities have been empowered to make by-laws for regulating and suppressing such nuisances, and there is every reason for supposing that full advantage will be taken of the clauses in the Act relating thereto."

JAPANESE WRESTLERS.

ALTHOUGH the American is willing to concede to the Japanese the possession of a mental capacity almost if not quite equalling that of the majority of white races, he is apt to form a somewhat slighting opinion of him as viewed from a physical standpoint. The specimens met with in this country do not tend to convey a favorable impression of their athletic powers. After, however, reading an account of the physical measurements of some of the most prominent Japanese wrestlers, a more respectful attitude regarding the muscular development of these little men will probably be taken. The *Jiji Shimpo* has recently published a table giving the measurements of six of the foremost Japanese fighters. From this table it is gathered that the most bulky of these modern gladiators weighs at the age of twenty-two years about three hundred pounds; height, five and a half feet; girth of chest, fifty-eight inches; lung capacity, four thousand four hundred and fifty cubic centimetres; upper arm, eighteen inches. Another one weighs over two hundred and eighty pounds; height, six feet five inches; girth of chest, forty-eight inches; lung capacity, six thousand cubic centimetres; upper arm, sixteen inches. The smallest of these fighting men weighs more than two hundred pounds, measures in height five feet seven inches, while in lung capacity he exceeds them all. There are few wrestlers or pugilists in this or any country who attain to these dimensions, and those who have seen some of the best exponents of Japanese wrestling are willing to back them when pitted against the pick of the European or American experts, as it is said that they are as skilful as they are powerful. — *Medical Record.*

Correspondence.

EXCESSIVE CRYING OF INFANTS.

BOSTON, August 28, 1898.

MR. EDITOR: There is no doubt that for a child under three months of age to be allowed to cry continuously for a considerable period of time is very injurious and even dangerous. Umbilical and femoral hernias are often produced in this way, as has been frequently proved. An instance comes to my mind of a child, now eight years of age, who during the first month of her life was subjected to this "system" of baby training, with the result that she has had ever since a discharge from the navel which the best surgeons in Boston have failed to cure.

The brain, too, must suffer from the continued hyperemia to which it is subjected. Digestion is impaired. The effect upon the lungs of forcible inspiration and expiration is to throw an unusual and unnecessary strain upon the delicate cell tissues that may well cause emphysema and lay the foundation of serious lung troubles. The blood cannot be well aërated and consequently becomes impure.

The heart, too, just commencing its life-long task of pumping blood into the circulatory system is seriously handicapped by the excessive strain upon it. Eczema and other skin diseases are caused by the united action of impure blood — the product of imperfect digestion and imperfect aëration — and the irritating perspiration caused by the long-continued exertion of crying.

These and many other evils are caused by excessive crying. Yet, there is an impression abroad that crying does not hurt a child, and that it is good practice to leave the child alone to "cry it out." In hospitals, where a certain routine must be enforced, some crying is inevitable and unavoidable, but in private nursing this routine is neither necessary nor desirable. A baby should be fed at regular intervals, and between the feedings it should receive such care as to make it comfortable and happy. It should be an axiom with every nurse that a baby cannot be treated too tenderly. It has come to my attention frequently that the converse of this treatment is being followed by many nurses, and, more strange still, is being encouraged by some physicians. The grounds upon which this cruel method is justified I understand to be as follow:

First, the child, from its birth, must be trained to regular habits. It must be fed, washed and dressed by rule; in the intervals let severely alone. If it cries take no notice of it.

Second, it doesn't hurt the child to cry.

Third, the mother will have more time for social pleasures if the child is trained so that it never expects to be hushed to sleep in her arms or to feel her comforting touch in its baby troubles.

All the above reasons, and they are the most reasonable reasons I have heard, have their origin in selfishness. None of them are given from the standpoint of the baby. The new-born infant rightly claims loving care, not neglect. It craves warmth and the protection of loving arms. It cannot change its position, but it appreciates the changes that a sympathetic nurse, who *feels* the baby needs, contrives to give it. No one but a sensitive, sympathetic nurse should ever attend upon an infant. Do not misunderstand me. I am not in favor of too much handling of an infant, and I would encourage regularity in diet and habits, but the attitude of the nurse towards the child should be one of fostering care and not that of machine-like adherence to rigid rules. I have known nurses to allow a child to cry until exhausted without making any effort to soothe it. To the physician belongs the responsibility of the health of the child. To the physician the nurse must look for orders. He is her superior officer, and must always be obeyed.

The undersigned would like to hear from physicians in regard to this matter. Do they approve or disapprove of this practice?

SUSAN E. CROCKER, M.D.

METEOROLOGICAL RECORD

For the week ending August 19th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,531; under five years of age 1,012; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 587, consumption 263, acute lung diseases 130, diarrheal diseases 394, typhoid fever 55, diphtheria and croup 50, whooping-cough 45, cerebro-spinal meningitis 15, scarlet fever 9, measles 9.

From whooping-cough New York 16, Philadelphia 8, Boston 5, Pittsburg and Providence 4 each, Cambridge, Lawrence and Everett 1 each. From cerebro-spinal meningitis New York 6, Baltimore 3, Philadelphia, Lynn and Somerville 1 each. From

scarlet fever Pittsburg 3, New York 2, Philadelphia, Baltimore, Worcester and Somerville 1 each. From measles New York 7, Philadelphia and Providence 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending August 12th, the death-rate was 24.3. Deaths reported 5,320; acute diseases of the respiratory organs (London) 163, diarrhœa 1,295, measles 127, diphtheria 71, whooping-cough 58, fever 24, scarlet fever 22, small-pox (Hull) 1.

The death-rates ranged from 13.6 in Huddersfield to 36.3 in Plymouth; Birmingham 27.0, Bradford 20.1, Cardiff 19.4, Gateshead 21.0, Hull 21.4, Leeds 21.3, Liverpool 33.6, London 23.7, Manchester 32.3, Nottingham 28.1, Sheffield 30.3, Sunderland 17.5, Swansea 17.6, West Ham 28.7.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 26, 1899.

C. H. GRAVATT, medical inspector, ordered to duty at the New York Navy Yard, as member of board of medical examiners, September 5th.

C. F. STOKES, passed assistant surgeon, detached from duty as member and recorder of board of medical examiners at the New York Navy Yard, September 5th, and ordered to continue on duty at the Naval Hospital, New York.

M. S. GUEST, passed assistant surgeon, ordered to the Boston Navy Yard.

S. ENGLANDER, pharmacist, detached from the Mare Island Navy Yard and ordered to the New York Navy Yard.

L. R. G. LEWIS, pharmacist, detached from the New York Navy Yard and ordered home and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING AUGUST 17, 1899.

IRWIN, FAIRFAX, surgeon. To proceed to Marseilles, France, and Lisbon and Oporto, Portugal, for special temporary duty. August 16, 1899.

WASDIN, EUGENE, surgeon. To report at Washington, D. C., for special temporary duty. August 14, 1899.

GEDDINGS, H. D., passed assistant surgeon. To proceed to New York, N. Y., for special temporary duty. August 16, 1899.

SMITH, A. C., passed assistant surgeon. To proceed to Hampton, Va., and report to Surgeon J. H. WHITE for special temporary duty. August 17, 1899.

STIMPSON, W. G., passed assistant surgeon. To report at Washington, D. C., for special temporary duty. August 17, 1899.

RICHARDSON, T. F., assistant surgeon. Detailed as quarantine officer for the port of Neuvitas, Cuba. August 14, 1899.

SCHUG, F. J., acting assistant surgeon. Granted leave of absence for thirty days from August 15, 1899. August 17, 1899.

WOODS, C. H., hospital steward. Granted leave of absence for fifteen days from August 16, 1899. August 15, 1899.

RICHARDSON, S. W., hospital steward. To proceed to Birmingham, Ala., for special temporary duty. August 17, 1899.

PECK, F. H., hospital steward. To proceed to Hampton, Va., and report to Surgeon J. H. WHITE for special temporary duty. August 14, 1899.

PROMOTION.

THURSTON, E. J., hospital steward. To be hospital steward and chemist. August 17, 1899.

BOARD CONVENED.

Board convened to meet at the U. S. Marine Hospital, New York, N. Y., at 10 o'clock A. M., August 16, 1899, for the physical examination of a candidate for appointment in the Revenue Cutter Service. Detail for the Board: Surgeon GEORGE W. STONER, Chairman; Assistant Surgeon W. C. HOBDY; Assistant Surgeon W. C. BILLINGS, Recorder.

TREASURY DEPARTMENT, OFFICE SUPERVISING SURGEON-GENERAL MARINE-HOSPITAL SERVICE.

WASHINGTON, D. C., August 25, 1899.

A board of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, October 4, 1899, for the purpose of examining candidates for admission to the grade of assistant surgeon in the U. S. Marine-Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: (1) physical, (2) written, (3) oral, (4) clinical.

In addition to the physical examination candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature and natural sciences.

The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination and will be commissioned in the same order as vacancies occur.

Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago or San Francisco.

After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon.

Promotion to the grade of surgeon is made according to seniority and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen-hundred dollars, passed assistant surgeons two thousand dollars and surgeons twenty-five hundred dollars a year. When quarters are not provided commutation at the rate of thirty, forty or fifty dollars a month, according to grade, is allowed.

All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service.

The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information, or for invitation to appear before the Board of Examiners, address

SUPERVISING SURGEON-GENERAL,
U. S. Marine-Hospital Service.

APPOINTMENTS.

The following appointments have been made at the Tufts College Medical School: HAROLD WILLIAMS, M.D., professor of the principles and practice of medicine; HENRY B. CHANDLER, M.D., professor of ophthalmology; HORACE D. ARNOLD, M.D., assistant professor of clinical medicine; ALBERT P. MATHEWS, S.B., Ph.D., assistant professor of physiology.

SOCIETY NOTICE.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION. – The twenty-fifth annual meeting of the Association will be held in Chicago, October 3-6, 1899. The officers of the Association are: President, Duncan Eve, Nashville; Secretary, Henry E. Tuley, Louisville.

RECENT DEATH.

SAMUEL B. WYLIE MCLEOD, M.D., died at his residence in New York on August 23d, of cardiac disease. He was born in 1831 in New York City, where his father, the Rev. John Neil McLeod, was pastor of the Twelfth Street Presbyterian Reformed Church for forty-four years. He was graduated from the University of Pennsylvania in the class of 1849, and from the College of Physicians and Surgeons, New York, in 1852. He continued his studies for a time in Paris and then served for two years as surgeon in the United States Navy. He then settled in New York, where he secured a large practice and took a prominent part in all the affairs of the medical profession of the city. He was especially interested in society work and was successively vice-president and president of the Medico-legal Society, the New York State Medical Association and the New York County Medical Association. Of the two latter societies he was one of the founders and he was elected president of the County Association for five terms in succession. He was also one of the founders and temporary president of the Medical Association of the Greater City of New York. At the time of his death Dr. McLeod was consulting physician to the Marion Street Lying-in Hospital, and trustee and consulting physician of the Northern Dispensary. He is survived by a widow and two sons, Lincoln McLeod, who was a captain in the 71st Regiment, New York Volunteers, in the Spanish War, and Dr. Johnston McLeod, a practising physician in Aurora, N. Y.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Organic Materia Medica, being a Guide to Materia Medica of the Vegetable and Animal Kingdoms, for the use of Students, Druggists, Pharmacists and Physicians. By John M. Maisch, Ph.M., Phar.D., late Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Seventh edition. Revised by Henry C. C. Maisch, Ph.G., Ph.D., Professor of Materia Medica and Botany in the Medico-Chirurgical College of Philadelphia, Department of Pharmacy. With 285 illustrations. Philadelphia and New York: Lea Brothers & Co. 1899.

THE EFFECTS OF TRAINING.

A STUDY OF THE HARVARD UNIVERSITY CREWS.

BY EUGENE A. DARLING, M.D., CAMBRIDGE.

(Concluded from No. 9, p. 209.)

Circulatory system. — Periodic examinations of the heart and pulse were made, special attention being given to the size of the heart, to the occurrence of abnormal sounds and to the rate and character of the pulse. Examinations were also made after several time-rows and both races.

Inspection of precordia, etc. — All of the men showed a prominence of the precordial region and a more diffuse pulsation than normal. The apex beat when visible was usually located in the fifth intercostal space, just inside the mammillary line. After the time-rows and races the apex beat was visibly displaced to the left, and in many instances a marked precordial and epigastric pulsation was noted. There was also in most cases visible pulsation in the peripheral arteries, most marked in the subclavians and carotids. The color was uniformly good, there being no instances of noticeable pallor or cyanosis, in spite of considerable disturbance of the heart's action in some cases.

Size of heart. — The routine examinations were all made in the middle of the afternoon, before rowing, so that the hearts might have recovered as far as possible from the rowing of the day before, and might be taken at their minimum size. Further examinations were made after the time-row of June 21st and after the races. The method pursued was as follows. The heart sounds were first examined and the apex beat located with the man standing. The man then lay flat and the apex beat was again located by sight and auscultation. Then, by combined auscultation and percussion, using the phonendoscope, the right, left and upper borders were found and outlined. The method is open to objection, as already stated, but seemed to be the most accurate under the circumstances, and by considering averages it was hoped that individual errors might, to a certain extent, be eliminated. The outlines were transferred to tracing cloth, the position of the nipples marked and the chart then made was kept for comparison. In measuring variations it was found that two fixed lines were necessary, one connecting the nipples — the intermammillary line — and the other bisecting the first at right angles — the median line of the chest. The ordinary terms employed clinically giving the position of the borders in relation to the sternum, ribs, or nipples are so variable in different individuals that no mean can be determined. The position of the apex beat was measured both from the median line and the intermammillary line; the right and left borders were measured from the median line, the former at the level of the nipples, the latter at the apex. The upper border was measured from a line drawn through the apex parallel to the intermammillary line. By averaging these various measurements it was easy to construct a chart representing the average heart of the squad and also to estimate the average variation.

The following Table (VI) and Chart (VI) give the measurements and variations of the average heart of the entire squad. They show that there was a progressive enlargement affecting both sides of the heart during May and reaching its maximum early in June. After this there was a considerable shrinkage, especially of the left side, both the left border and the apex beat receding towards the median line until their positions were not very different from those of early May. The right side of the heart also showed shrinkage but to a less degree than the left. The position of the upper border varied considerably in the different examinations, depending apparently partly on the fulness of the stomach and partly on the depth of respiration. The relative rise and fall of the apex beat could not be followed as closely as its lateral movement, owing to the ribs.

The period of greatest enlargement corresponded to the period of the most arduous work, late in May and early in June, when the final selection of men was being made, and when consequently every man

TABLE VI. Average Heart Measurements of Squad.

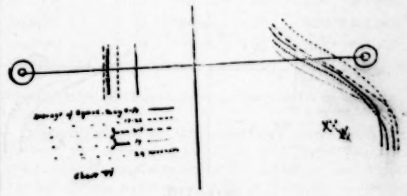

CHART VI.

was pulling his hardest. Probably the individual strain was greater at this time because the crew had not yet learned to pull as a unit. Then too, as already mentioned, the weather was very unfavorable, and the effort required to do the work was considerably greater than was needed later. The better weather conditions prevailing at New London, the more uniform rowing as the form of the crew was perfected and the more accurate adaptation of each man's rigging to his peculiarities, all tended to lessen the strain on the individual oarsman and by enabling him to do his work with less muscular effort proportionately diminished the labor demanded of the heart.

How much of the enlargement was due to hypertrophy and how much to dilatation is difficult to say. Probably there were both hypertrophy and dilatation. The accompanying change in the heart sounds in certain cases to be descr bed later would indicate that there was considerable dilatation at first, but that sub-

sequently the hearts gradually recovered tone and a true compensatory hypertrophy took place.

During the races, both four-mile and two-mile, a considerable dilatation took place, as shown in Charts (VII) and (VIII). The average increase in breadth of the cardiac dulness was nearly the same in the two crews — 1.4 centimetres for the eight and 1.5 centimetres for the four. The marked rise of the upper border relative to the intermammillary line may be attributed to the fact that the examinations after the race were unavoidably delayed until after dinner, and consequently allowance must be made for the full stomach.

Heart sounds. — The twelve men in the squad may be divided into three groups according to the effect of the training and races on their heart sounds and action.

In Group I, numbering five men, may be placed those whose hearts developed no markedly abnormal condition. The pulse rate at rest varied from 60 to 80, and after the time-rows and races, rose to 120 or thereabouts. The sounds remained normal, except that the first sound became somewhat louder

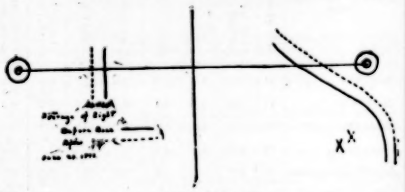

CHART VII.

CHART VIII.

and rougher than normal. Both the first and second sounds were occasionally reduplicated.

In Group II, including two men, the routine examination showed nothing abnormal, but after the time-rows and race both developed a faint blowing systolic murmur, loudest at the left margin of the sternum in the second and third intercostal spaces, but also audible at the apex. As in Group I, there was some tendency to reduplication of the sounds, but the rhythm remained normal.

In Group III may be placed the remaining five men, whose hearts showed abnormalities of sound or action at several different examinations, both before and after unusual effort. The most extreme case deserves a detailed description. This man had had rheumatism and typhoid and had been informed several years before that his heart was weak.

Following are the notes as taken:

May 10th. Pulse 96; irregular. Diffuse precordial and epigastric pulsation; pulmonic second sound accentuated; blowing systolic murmur audible over entire cardiac area, loudest in pulmonic area and at apex.

May 18th. Pulse 84; irregular; heart sounds as above but murmur inaudible at apex.

May 25th, after time-row of 3¾ miles. Pulse 138; very irregular; two sounds of equal intensity at apex; rhythm embryonic; murmurs very loud over entire precordia.

May 30th, before time-row. Pulse 84, somewhat irregular; murmur faint. After time-row of 3¾ miles. Pulse, 128; fairly regular; murmur much fainter than after previous time-row.

June 7th. Pulse 88; sounds as before time-row of May 30th.

June 17th. Pulse 78; regular; murmur very faint.

June 21st. Pulse 82; regular; no murmur. Two hours and a half after four-mile time-row. Pulse 98; regular; no murmur.

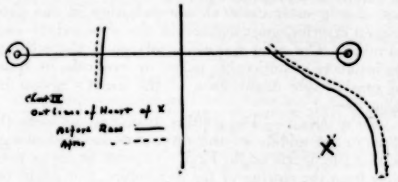

CHART IX.

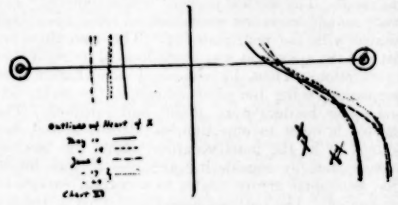

CHART X.

June 29th, before race. Pulse 84; regular; no murmur. Three hours after race. Pulse 88; murmur audible but very faint. General condition excellent.

The changes in the size of this heart corresponding to the changes in sounds and action are shown in Chart X, while the comparatively slight increase during the race itself is brought out in Chart IX.

The gradual improvement in this heart was one of the most instructive points in the entire investigation. After the time-row of May 25th it was in bad shape. The irregularity, accentuated pulmonic second sound, embryonic rhythm and rapid action, together with the enlargement, which was well marked, all pointed to an acute dilatation. During June the establishment of a compensatory hypertrophy was indicated by the return to normal rhythm and rate, the practical disappearance of the murmur and the stationary size. With all the disturbance shown by examination of this man's heart, there was nothing in his appearance

or capacity for work which would have called attention to his heart. If he had been advised to stop rowing when his heart was first examined the best demonstration of the beneficial effects of training would have been missed and the crew would have lost a very valuable man.

The four other hearts in this group showed much the same conditions, though in a less degree. All finished the race in good condition and without any more exhaustion than their companions.

Pulse. — The character and rate of the pulse have already been mentioned in several instances, and it is only necessary to add that it was invariably of high tension after unusual effort. This was no confirmation of Williams and Arnold's observation of diminished tension in the Marathon runners. It is possible that the exhaustion of the latter was extreme, and their hearts may have been much more affected than was the case with the crews. It is to be regretted that circumstances forbade the taking of sphygmographic tracings.

The cause of the murmur in acutely dilated hearts is ably discussed by Williams and Arnold; no evidence was secured in this study opposed to their conclusion that the bruits are of mitral origin and are due partly to a relaxation of the circular muscular fibres surrounding the orifice and partly to fatigue of the papillary muscles which control the movements of the valve-cusps.

The chief deduction to be made from this study of the hearts is that the heart is a muscular organ and that it shows with the other muscles both the fatigue due to violent and prolonged exertion and also the increase in size and power due to proper exercise and nutrition. The fatigue results in dilatation, the increased power in hypertrophy, and one of the main objects of training is the establishment of this hypertrophy. The physiological capabilities of the heart are enormous, and in judging of the effect of any undue exertion on it we must not regard the murmurs and irregularity alone, but must also consider carefully the way in which the heart is doing its work, its strength, as shown by its ability to maintain a proper arterial tension, and its recuperative power. As with other muscles, not size but quality tells in the long run.

Kidneys. — Periodic examinations of the urine were made coincidently with the heart examination. An attempt was made to estimate the twenty-four-hour amount, specific gravity, urea percentage and total urea, to test for albumin and sugar and to examine the sediment microscopically. The figures given below, as far as they refer to the twenty-four-hour amount and calculations based thereon, are probably considerably less than they should be. Even with the best intentions, slips of memory were liable to occur, and the full amount of urine passed was not always saved. Perhaps ten to twenty per cent. should be added to the urea excretion for this reason.

The urea was estimated by Squibb's ureometer. For albumin both the nitric-acid and heat tests were employed, and in case of doubt the picric-acid test was resorted to. When an appreciable amount was found, Esbach's albuminometer tube was used. The sugar test used was Fehling's.

The main facts ascertained are summarized in Table VII, subject to correction as noted above. These figures denote a moderate increase in the urea secretion above the normal and by implication a moderate increase in nitrogenous metabolism, but by no means as great an increase as one would expect if all the proteids eaten were absorbed and utilized. Physiologists have proved that an increase in the urea elimination above normal limits is usually caused by an increase in proteid digestion and not by an increase of muscular action.

Sugar. — The tests for glucose were invariably negative.

Albumin. — An unexpected fact brought out in the routine examination was the presence of traces of albumin in the urine of a large proportion of the squad under ordinary conditions of training. The twenty-four-hour amounts were examined six times, the tests being made intentionally only after a lapse of several days after the time-rows, to eliminate their effects as far as possible. In 83 specimens examined albuminuria was present 48 times. The amount of albumin was never more than a trace.

Sediments. — The albuminuria was, with but few exceptions, always accompanied by renal casts and epithelium and occasionally by a considerable excess of leucocytes. In several instances a few casts were found in urines which gave negative albumin tests. In the few cases of albuminuria without casts partial decomposition had taken place before the microscopic examination, so that casts may have been present but obscured.

Table VII. Average Urine Tests.

Date.	No. exam.	24-hour amount.	Specific gravity.	Urea, %	Total urea.

Albuminuria after time-rows and races. — After three of the time-rows and after both races the first urine passed was examined for albumin and casts. The specimens were all small in quantity — one to three ounces — highly concentrated, and invariably contained considerable amounts of albumin, as shown in Table VIII. The largest percentage observed (0.9 per cent., Esbach) was in the urine of one of the four-oared crew after the two-mile race. The sediments contained correspondingly large numbers of hyaline and finely granular casts, many having renal cells and red blood corpuscles adherent. In many of the sediments there was also a considerable number of red blood corpuscles and an excess of leucocytes. The sediment in many cases was exactly that of the first stage of acute nephritis, and if examined without a knowledge of the conditions might easily have caused anxiety.

To find out how long the albuminuria and casts continued after the time-row of May 30th single specimens were examined the following day before the afternoon row, with the result that of 14 samples two contained a trace and one had 0.025 per cent. It is regretted that tests were not made after the rowing on ordinary days, since it is probable that even this may have caused an appreciable albuminuria and that

the traces found in the twenty-four-hour specimens really represented a considerable amount of albumin passed in one urination after rowing, diluted with non-albuminous urine passed during the rest of the day.

The renal conditions may be interpreted as an active hyperemia, becoming intense during the time-rows and races, and dependent in all probability on the increased arterial tension. Whether the hyperemia ever leads to permanent changes in the kidneys is a matter for future investigation.

The blood. — Numerous estimates of the specific gravity of the blood were made by Hammerschlag's method, with the intention of making blood counts and hemoglobin tests should any variation from the normal be observed. The method, however, was found to be tedious and unreliable, the results varying according to the temperature. In several instances when the specific gravity was low — 1.050 or thereabouts — a blood count and hemoglobin test gave normal figures. The examinations made yielded no information of importance and were therefore discontinued.

The digestive system. — One of the most troublesome features in training of all kinds is the care of the digestive organs. Many a race has been lost because of weak stomachs and because of prostration due to diarrhea. The crew squad this year offered no exception to this common tendency, for there were several cases of temporary attacks of indigestion and diarrhea. These troubles ought not to be attributed to the training but to improper diet and methods of eating. The food provided was all that could be desired in quality and in preparation. The chief criticisms suggested were in regard to the selection of food by the men themselves and to their common habit of eating too much and too fast — faults not confined to crewmen but nevertheless unwise. The one aim of many of the men seemed to be to consume as much meat as they could get and in the shortest possible time. The amount of roast beef devoured at a single meal was astonishing, a man often disposing of five or six large slices.

It has already been pointed out in discussing variations in weight that the energy set free in muscular exercise is derived largely from the combustion of fat and carbohydrate material, while the proteid metabolism is directed chiefly to repairing waste. To use a rough illustration, if we regard the body as a machine, the proteid elements of the food go largely to replace the wear and tear of the machine itself, while the carbohydrates and fats furnish the fuel whose combustion liberates heat and energy and thus enables the machine to do work. Of course the body is not a machine and this comparison is not true except in a general way. During training the wear and tear of the body generally is much increased, and the proteid elements of the food must be increased accordingly, but it is an error to increase them so enormously as is frequently the case. The slight increase in the urea excretion indicates that much of the proteid material must pass through the digestive tract unassimilated. This throws a great deal of extra work upon the digestive organs, work which does no good to the body, but may, and undoubtedly often does, do harm in causing indigestion and diarrhea.

The subject is deserving of study based on analyses of the food and of the excretions. A more accurate adjustment of food to needs and more time spent in mastication would unquestionably prevent that sensitiveness of the digestive organs which is one of the bugbears of the trainer.

III. OVER-TRAINING.

It was hoped that during this investigation data might be obtained bearing on the subject of over-training, but unfortunately (or fortunately, according to the point of view) there were no typical cases to study. The common symptoms are well known. They are, in brief, a loss of strength and endurance, so that a man previously strong becomes incapable of prolonged effort. This may be accompanied by a general nervous restlessness, by listlessness, by a loss of weight, by insomnia and by various digestive disturbances, such as anorexia and diarrhea. These symptoms should not be confounded with the temporary collapse which is occasionally seen after a severe exertion and which is more apt to be due to under-training than to over-training. The real condition at the bottom of over-training is still obscure, but in the light of this inquiry certain possibilities are suggested as factors which may have to do with its causation.

The first and most obvious one is the condition of the heart. We have seen that a great increase in size and strength is demanded of this organ and it may easily happen that it is called upon for more work than it is able to do and that instead of establishing a compensatory hypertrophy it becomes dilated and weakened. A "broken-winded" athlete is probably one with a dilated, flabby heart.

The second possible factor is the condition of nutrition. This is more difficult of demonstration than the first. As already pointed out, the nutrition may be disturbed in two ways, either by an improper diet, in which the nutritive elements are not apportioned to the needs of the body, or by disturbed digestion, as a result of which the food taken into the body is not utilized. That both of these contingencies may occur has been sufficiently demonstrated.

TABLE VIII. Albuminuria after Time-rows and Races. Figures Represent Percentages by Esbach's Albuminometer.

The third factor may be simple overwork. This is not so likely as the two preceding, for, when properly nourished, the capacity for work on the part of healthy young men is certainly much greater than that demanded in training. The peculiarity of training work, however, is its concentration. It may be that the excessive work accomplished in a brief space of time exhausts the muscles so that they do not recuperate before being called upon for a repetition of the work — that there is, so to speak, an accumulation of fatigue, and that this constitutes over-training.

The fourth factor which suggests itself is a nervous one, and this, while more intangible than the others, is unquestionably an important one. In the present state of our knowledge it can only be surmised, not proved. It is well known that there is a nervous fatigue entirely distinct from muscular fatigue and resulting from prolonged anxiety, from monotony of work and from numerous other causes. It may be that anxiety about a coming contest, together with the prolonged mental strain of mastering the technicalities of such a difficult art as rowing or such a complicated game as football, may lead to a condition of nervous exhaustion, and that this nervous exhaustion contributes to over-training.

No one of these factors will account for all cases of over-training and probably more than one cause must be admitted. At any rate it is safe to suggest certain points which should be borne in mind in laying out any course of training. They are, (1) not to throw too much work upon the muscles and especially upon the heart, until they are strengthened by preliminary work; (2) to watch the nutrition carefully, and (3) to avoid nervous fatigue by providing a certain variety of exercise, and by not confining the attention too closely to the approaching contest.

Finally, this investigation has demonstrated that the physiological effects of training, on the heart and kidneys in particular, may approach unpleasantly near to pathological conditions, and that there should be some competent supervision to insure that the safe limits, when those are determined, shall not be passed.

TWO CASES OF INJURY OF THE CORD RESULTING FROM FRACTURE OF THE SPINE.[1]

BY JOHN JENKS THOMAS, A.M., M.D., BOSTON,
Assistant in Nervous Diseases, Boston City Hospital; Assistant Neurologist, Children's Hospital, etc.

The literature of fracture of the spine within the last few years has reached an enormous volume, and a number of important monographs upon the subject has been published, such as that of Wagner and Stolper, and that of Kocher. Yet it is surprising to find in how few cases careful pathological examinations of the cord have been made. This was done in very few of Bastian's cases, and the same is true of those of Thorburn. In Germany more of this work has been done by Bruns and others. In this country the earliest cases I have found, where a careful microscopical examination was made, are those of Herter, while in Boston the first case was that reported by Dr. Courtney and myself in the Ninth Series of the Medical and Surgical Reports of the Boston City Hospital. In view of these facts I have thought that these additional cases would not be without value. The two cases reported in this paper were both of injury of the cervical region of the cord, and were admitted to the Boston City Hospital, one under the care of Dr. Monks, and the other under the care of Dr. Munro, to whose courtesy I am indebted for the clinical notes of the two cases.

[1] From the Pathological Laboratory of the Boston City Hospital. — Read before the Boston Society for Medical Improvement, May 8, 1899.

Case I. The first patient was a man thirty-seven years of age, who entered the hospital September 24, 1898. He had been found at the foot of a flight of stairs, and the record states that he had probably fallen three stories. He was semi-conscious at entrance and could be roused. On examination it was found that the patient could turn the head from side to side. There was an indefinite swelling of the neck, with marked tenderness and pain on motion. There was a lacerated wound over the outer side of the right patella, which connected with the joint. Motion was lost in the lower limbs, and sensation was absent over the limbs and trunk, except over the upper part of the chest. The pupils were equal and reacted to light. The superficial and tendon reflexes were absent. The breathing was with the diaphragm, and on the night of the 25th and 26th there was present Cheyne-Stokes respiration. It was noted on the 26th that he could move the left arm a very little, and on the 28th it was added that sensation was normal over the face, neck, and on the outer side of the arms down to the elbows. The patient had to be catheterized, and at first the bowels moved only after the use of enemata, but on the 30th incontinence of feces was noted. The temperature rose on the 25th, and on the 30th it was 104° F. On October 2d the patient became unconscious, and died upon that day.

The autopsy was made by Dr. Mallory on October 3d, eighteen hours after death. The spinal canal only was allowed to be opened. The body was that of a large, well-built and muscular man. On cutting away the subcutaneous tissue around the upper dorsal and cervical vertebræ there was found only the slightest trace of hemorrhage. This was present around the atlas, and also in the close vicinity of the lower cervical vertebræ, and of one or two of the upper dorsal vertebræ. There was a comminuted fracture of the fourth, fifth and sixth cervical vertebræ. The fracture involved the spinous processes, and the laminæ on both sides. On carefully removing the posterior portions of the cervical and the upper dorsal vertebræ it was found that the dura was attached by easily broken adhesions to the lower cervical vertebræ. The dura was tense, and swollen in the cervical portion. On opening it longitudinally there was found in the centre of the cervical enlargement an area three centimetres in length, which was soft and of a slightly yellowish color. The substance of the spinal cord was to a slight extent diffluent. The dura above and below the enlargement contained quite a little clear serous fluid. The cervical enlargement extended two centimetres above and two centimetres below the area of softening, and so far as could be made out externally, was practically normal, except possibly for a little swelling. The bodies of the fourth and fifth cervical vertebræ projected upwards into the spinal canal. The bodies were split longitudinally, as was also the body of the sixth cervical vertebra. The bodies of the fourth and fifth cervical vertebræ seemed to have other fractures in other directions, but they could not be distinctly made out.

Anatomical diagnosis. — Comminuted fractures of the spinous processes, laminæ and bodies of the fourth, fifth and sixth cervical vertebræ; laceration of the cord opposite the fourth and fifth cervical vertebræ with acute softening.

After hardening in formalin, section of the cord through the softened area at the middle of the cervical enlargement showed no sign of the normal structures of the cord. This condition extended for nearly one centimetre above and below the first section. A section 1.5 centimetres above the first one showed a large oval area, darker in color than normal, occupying the position of the left posterior horn, and the left posterior column, and extending well forward into the base of the left anterior horn. About two centimetres below the first section there was a similar dark area, smaller than that just spoken of, which occupied the base of the right anterior horn. About 1.5 centimetres lower, at the lower part of the cervical enlargement this dark area was larger, and still in the right side, but more in the posterior horn, and a similar smaller area was seen in the root of the left posterior horn. Half a centimetre lower the cord on section appeared normal to the naked eye.

Microscopical examination. — Sections were made at various levels and stained with hematoxylin and eosin; hematoxylin and Van Gieson's picric-acid and acid-fuchsin stain; by Weigert's myelin-sheath stain; Pal's modification of this followed by picric acid and acid fuchsin; and by Marchi's method.

At the point of greatest softening, at the level of the fourth cervical segment, it is almost impossible to make out any of the normal structures of the cord. At the periphery there can be seen a few nerve fibres with normal appearing nerve sheaths, but most of the fibres are swollen, and those that are cut transversly are mixed with others cut in all directions, and evidently broken and disorganized. Here and there throughout the section are areas of hemorrhage, composed of masses of red blood corpuscles with a moderate number of leucocytes. These corpuscles do not stain distinctly and are plainly undergoing degeneration. Here and there a blood-vessel is seen, often surrounded by a collection of leucocytes with irregular vesicular nuclei, and by small round cells. Occasionally at the periphery of the cord a connective-tissue septum, or connective tissue about a blood-vessel can be traced for a short distance into the substance of the cord. The greater part of the cord is represented by a confused mass in which are very numerous large and small phagocytic cells, apparently endothelial or connective-tissue cells. These cells for the most part have single rather small vesicular nuclei, eccentrically placed at the periphery of the cell. Occasionally cells are seen with two, three, or even more nuclei, or with a horseshoe-shaped nucleus; the protoplasm appears coarsely granular, and frequently contains fragments of red blood corpuscles or whole corpuscles. Sections stained by Marchi's and by Weigert's methods show that these cells have taken up large amounts of fat, and also myelin. At this level of the cord no nerve cells can be recognized. The sections stained by Marchi's method show a large amount of degenerated myelin throughout the section, aside from that taken up by the phagocytic cells spoken of above. These masses of fat vary greatly in size, some small, others large, and round or irregular in shape, and occasionally rings of various sizes are seen, representing degenerated and swollen nerve sheaths. Both the anterior and posterior nerve roots show the presence of a large amount of fat, fully two-thirds of the fibres being affected. Both the myelin sheaths and the axis cylinders show the presence of fat.

Sections one and a half centimetres above the point of greatest destruction show that the dark area in the left posterior horn consists chiefly of red blood corpuscles, which stain poorly and are evidently necrotic. There is a large amount of brownish blood pigment lying free throughout this area. There are numerous larger and smaller phagocytic cells, similar to those spoken of above, many of which contain blood pigment and red blood corpuscles. Very rarely a leucocyte can be seen. Here and there are large, round homogeneous masses, staining faintly with hematoxylin, apparently greatly swollen axis cylinders. There are quite numerous, rather large, round or oval empty spaces throughout much of this area, apparently formerly occupied by swollen nerve fibres. This area of hemorrhage is fairly sharply bounded, and occupies nearly the whole of the left posterior horn and the left half of the posterior columns, extending nearly to the periphery of the cord, and almost to the central canal anteriorly. Here and there in this area are seen small blood-vessels, with normal walls, without infiltration about them, but these are the only normal structures that can be made out. Sections from this level stained by Weigert's and Marchi's methods show that the phagocytic cells have taken up a considerable amount of myelin and fat, and that there are numerous large, fatty masses and rings, and swollen myelin sheaths scattered irregularly throughout this area. The other portions of the cord at this level appear fairly normal, except that scattered throughout the white substance of the cord, more especially at the periphery, there are to be seen swollen faintly staining nerve fibres, and portions of the periphery of the cord appear edematous. There are also at various places, more especially in the gray matter, enormously dilated blood-vessels to be seen. The sections stained by Marchi's method show a moderate degeneration of nerve sheaths and fibres throughout the cord, not more marked in one area than in another, except that it is perhaps slightly more marked near the periphery of the cord. There is a quite extensive degeneration of both anterior and posterior nerve roots, though less extensive than in the sections made at the point of greatest injury to the cord.

Sections from a level one and a half centimetres below the area of greatest injury, from about the region of the eighth cervical segment, show a similar area of hemorrhage, but somewhat smaller, in the right posterior horn, extending well forward to its base, and somewhat into the right posterior column. Here, too, there are some greatly dilated blood-vessels in other regions of the cord, chiefly near the central canal, and a diffuse degeneration of the nerve fibres of the white substance of the cord, and of the anterior and posterior nerve roots, as shown by Marchi's method.

Sections from the mid-dorsal region and the lower dorsal region show nothing abnormal except a slight degeneration of nerve fibres, about equal in all parts of the white substance of the cord, and a slight degeneration of the anterior and posterior nerve roots. There are no hemorrhages into the pia.

Summary. — We find in this cord at the mid-cervical region, extending over the fourth, fifth and sixth cervical segments, a very extensive destruction of all parts of the cord, partly from hemorrhage into the substance of the cord, and partly due in all probability to a direct crushing of the cord, resulting in breaking down of the nervous structures, a condition sometimes called myelomalacia. Although at the periphery some apparently normal fibres are seen, it is doubtful whether these were capable of functionating, and we probably had in this case a lesion which produced the symptoms of a total transverse lesion of the cord. The presence of phagocytic cells shows that the process of absorption of the destroyed tissues had begun. Above and below this area for quite a distance, there was extensive hemorrhage into the gray matter of the cord, chiefly in the posterior horns, though the white substance of the posterior columns was seriously affected. That is, we have, in addition, a traumatic hematomyelia. Other levels of the cord showed a diffuse degeneration of nerve sheaths and axis cylinders to about an equal extent in both ascending and descending tracts both above and below the crushed portion, and also degeneration of both anterior and posterior nerve roots. No degeneration of tracts of the cord was shown by Weigert's and Pal's stains, probably because a sufficient interval of time for their development had not elapsed. There were no hemorrhages in the pia.

Case II. The second patient was a man who entered the Boston City Hospital on October 31, 1898. The record simply states that he had fallen down stairs. Upon examination there was found a slight abrasion of the left side of the head and face, but no signs of fracture of the skull. The pupils were equal, of normal size, and reacted to light. The examination of the spine showed nothing except marked tenderness over the spinous processes of the third, fourth and fifth cervical vertebræ. There was paralysis of the arms and legs, with slight involuntary movements of both arms and of the right leg. It is stated that the left leg showed muscular spasm. There was complete loss of sensation in the body below the fifth rib, as well as in both forearms, and much diminished sensation in the arms and shoulders. The knee-jerks were much diminished. The cremasteric reflexes were present. The pulse was 70, and of good strength and volume. The temperature was 97.8.° The examination of the urine showed nothing abnormal. At the operation the laminæ of the seventh, sixth and fifth cervical vertebræ were removed. No fracture was found, and no hemorrhage either extra- or intra-dural. The dura was very tense, and darker in color than normal, and on being pricked, clear fluid spurted out with much force. No evidence of pressure upon the cord was found so far as could be told by exploring with a probe. Pulsation returned after the evacuation of considerable fluid. The cord felt normal to the touch. On November 2d it was noted that the patient could move the arms slightly, and that there was a questionable improvement in sensation. The temperature, however, rose that afternoon, and the patient became delirious and died at ten o'clock that evening.

The autopsy was made by Dr. Mallory the next morning. Only the spinal cord could be examined. The body was that of a large and well-built man. There was an incised wound in the median line of the lower part of the back of the neck, about seven centimetres long. On laying open the vertebral canal, the spinous processes and posterior laminæ of the fourth, fifth and sixth cervical vertebræ were found to have been removed by the surgical operation. The walls of the opening leading into the vertebral canal were grayish in color. There was apparently no pus present. On laying open the vertebral canal a small amount of dark red material was present on the posterior surface of the cord, apparently blood and fibrin. After removing the cord, and opening the dura along the posterior surface, there was found in the cervical portion, 2.5 centimetres above the operation opening into the vertebral canal, a slightly depressed bluish line encircling the cord. On pressure at this point the tissue was softer than the tissue above and below. This linear area of softening was situated about opposite the third cervical nerve. There was no swelling of the cord and no hemorrhage. Examination of the bodies of the vertebræ revealed no signs of fracture.

Anatomical diagnosis. — Softening of the cord.

After hardening in formalin the cord showed distinctly the band of softening at the third cervical segment, not more than two millimetres in width. On section through this area there was a dark area in the centre, more marked in the region of the anterior horns, which could be seen extending about half a centimetre in the anterior horns, both above and below the area most damaged, but extending a little further in the right anterior horn than in the left one. Sections through other regions of the cord showed nothing abnormal.

(To be continued.)

THE ROLE OF THE STAPHYLOCOCCUS IN SKIN DISEASES.[1]

BY CHARLES J. WHITE, M.D., BOSTON.

One cannot attend a daily skin clinic without being struck with the frequency with which pus is encountered in the many various diseases which are presented for diagnosis. The conditions where pus is present may be divided into two categories; (1) where the disease is primarily and essentially of pustular origin; and (2) where pus is a secondary element due to accidental inoculation. In the first division we find impetigo, sycosis (non-tricophytica), ecthyma, furunculosis, abscess and carbuncle; and in the second I mention especially acne, impetiginous eczema, some forms of dermatitis, scabies, certain varieties of iodide and bromide eruptions, and afterwards the primarily vesicular and bullous affections and all cutaneous diseases where pruritus and subsequent scratching play a part. To show a little more precisely how important a place our first division occupies in skin clinics, let me quote a few figures from the returns of the American Dermatological Association, which date from 1877, and of local interest from the records of the skin department of the Massachusetts General Hospital. From the former source we find that the group impetigo, sycosis, ecthyma, furunculosis, abscess and carbuncle constituted 5.19 per cent. of all skin diseases recorded, and from the latter records we learn that these same dis-

[1] Read before the Massachusetts Medical Society, June 13, 1899, and recommended for publication by the Society.

cases comprised 0.6 per cent. of all the cases observed. As to the precise figures in the secondarily pustular affections it is impossible to speak, as of course there are no such minute statistics in existence. Suffice it to say that in my investigations the secondarily pustular diseases were exactly twice as numerous as the essentially pustular affections.

Now what is the etiological factor in this important class of dermatoses? Before mentioning the results of any personal work let us see what the more important investigations of others have recorded in this connection, and let me acknowledge here my indebtedness to Unna and to Wickham for many of the extracts which I shall make in the following paragraphs.

In 1877 Vidal made some inoculations from cases of impetigo and concluded his monograph by asserting the possibility of reproducing this disease by inoculation — a fact which, in his mind, established impetigo as a definite dermatological entity. This was, I think, the first experimental work done in connection with this disease. Hebra had never allowed the existence of impetigo as a separate disease, but had considered it a variety of eczema. Tilbury Fox in 1862 had, however, paved the way clinically for the many subsequent investigators, among whom Vidal was the first, as above stated. Three years later, in 1880, Unna produced an essay claiming the inoculability and autoinoculability of impetigo and differentiated it from eczema. In 1881 Crocker found chains of cocci in microscopical specimens from impetigo. In 1885 Eichstedt described an epidemic of impetigo in 76 out of 79 children recently vaccinated in Rugen, and considered the affection as a definite one which was inoculable only by intimate contact. This same year Dewérve made a series of inoculations from all products of impetigo and succeeded often in obtaining cultures. Eight years later, in 1893, this same writer produced impetigo artificially by rubbing lice from an impetiginous child upon the skin of a healthy child, and concluded that pediculi were the carriers of the disease — an observation to which many recent writers would agree, although Unna claims merely coincidence.

Bockhart, in 1887, established the extremely important fact — one which Unna characterizes as epoch-making — that from an inoculation from impetigo, one could produce impetigo, folliculitis and furunculosis. This assertion has been verified by other observers, and, I think, has been denied by none. Bockhart thus claimed that several diseases, hitherto considered separate and distinct entities, were practically one and the same, that one could pass into another and that the clinical forms were due to a difference in soil, seat and individual, and not to a separate etiological factor. Bousquet two years later proved that these diseases were due to cocci and reiterated the statements of Bockhart. A few months later Dubreuilh — Bousquet's master — said that "the staphylococcus aureus and perhaps the albus were the pathogenic organisms," and claimed that there is only one impetigo and that it is inoculable; that furuncles are of the same origin, but lie at a different level of the skin; and that the pustules of scabies are etiologically similar to impetigo and to furunculosis.

In 1890 and 1891 Leloir described many inoculations from cases of impetigo and found only staphylococcus pyogenes aureus or albus and concluded that all forms of impetigo were inoculable. The following year Leroux continued the work and isolated staphylococcus aureus, albus and citreus and a peculiar form of streptococcus. Dupray spoke only of staphylococci in his thesis in 1891, and some months later Wickham came to similar conclusions in an excellent monograph, from which I shall now quote at some length.

Wickham found that on inoculating from impetigo, first from vesicle, then from pustule, then from crust, and finally from excoriation under the crust even after disinfection with alcohol, pure staphylococci resulted each time, and concluded: (1) that staphylococci are found in all secretions of impetigo, in the vesicles as well as in the pustules; (2) that the staphylococci exist in abundance in the inflamed tissues, and that they are in the serous exudations even at the moment of their issue; (3) and that each variety of staphylococci can be met with alone or in company with another variety. Wickham inoculated himself on one forearm with the albus and on the other with the aureus. In three days a few miliary pustules appeared, which quickly disappeared. He then took a culture of aureus and albus from a non-tricophytic sycosis and one from a purulent zoster and inoculated himself again and found the same results, from which he decided that he did not offer a suitable soil, so he repeated the experiment on a strumous child and produced a typical impetigo contagiosa, which began as an erythema and incipient vesicles within two days and went through the stages of pustulation and crust formation. He then concludes: (1) that the inoculation of cultures of staphylococci can reproduce complete impetigo; (2) that the inoculation of staphylococci, whether aureus or albus, produces analogous lesions; (3) that the staphylococci of impetigo are identical with those of other suppurations, that is, sycosis, pus of secondary infection; (4) that certain subjects are rebellious to inoculations and that to succeed one must have great perseverance and irritate the skin violently and apply thick layers of micro-organisms; and (5) that a lymphatic soil predisposes to impetigo.

In concluding his monograph, Wickham writes: (1) That certain affections described heretofore as separate diseases — such as impetigo, sycosis non-tricophytica, paronychia, ecthyma, furuncle, folliculitis and carbuncle — are sister maladies, of the same essence; and that the same micro-organism can produce one or another of the aforesaid diseases; (2) that several of these diseases can be found united in the same individual; (3) that therefore none of these affections should be given a special designation, but these diverse affections are not special entities but only pathological forms of a cutaneous malady, more general, polymorphous *par excellence*, produced by the staphylococcus, and to which it would be suitable to give such a name as staphylococcia purulenta cutanea.

In 1893 Kurth was the first of the modern investigators to associate streptococci with the name of impetigo. Kurth considered staphylococci only as companions of his streptococcus, which differed in many ways from the streptococcus of Fehleisen. Three years later Brochet published results of a similar nature, but to many his streptococcal theory would appear invalid, since re-inoculations from his isolated streptococci produced a lymphangitis and not an impetigo or a folliculitis. Brochet, however, differed from Kurth and others in that he considered his

streptococcus to be the same as that of erysipelas, only in an attenuated form.

In 1896 Armstrong observed a series of impetigo cases in Edinburgh football players, and stated that staphylococci were the active agents in the disease. In the following year Balzer and Griffon studied 31 cases of impetigo and 14 of ecthyma, and satisfied themselves that streptococci were the cause of the infections, but re-inoculations produced abscess, erysipelas and fatal septicemia, and not the original diseases.

Two years ago Curry conducted a series of pathological investigations, and from his results I quote those which apply to the question we are considering. In 6 pustules he found that 4 were due to the staphylococcus pyogenes aureus, 1 to the bacillus of diphtheria, and 1 to the bacillus pyocyaneus. [I would say that the diphtheritic pustule was due to an accidental inoculation from a case of that disease, and is therefore a case by itself.] In 6 furuncles Curry found that 4 were due to the staphylococcus aureus, 1 to the streptococcus and 1 to the bacillus pyocyaneus. In 3 cases of felon he found only the staphyloccus, in 3 carbuncles a similar result, and in 18 abscesses he showed that 13 were due to the aureus, 4 to the albus and 1 to the streptococcus. This year Corlett found, on examining 9 cases of impetigo, that 3 were due to the staphylococcus aureus, 3 to the albus and 3 to the aureus and albus together.

Thanks to the kindness of Dr. R. M. Pearce, I was allowed to examine the Surgical and Medical Reports of the Pathological Laboratory of the Boston City Hospital, and from them I have selected 1 case of sycosis, 3 of furunculosis, 2 of carbuncle and 95 of cutaneous abscess. The 6 cases of sycosis, furunculosis and carbuncle were due to pure infections of staphylococcus aureus, and in 79 of the 95 abscesses, that is, in 83 per cent., the staphylococcus in some form was found in a pure state or in conjunction with one or more organisms. To be more precise, I append this table of the analysis of the bacterial examination of the 95 abscesses: In 31 cases the staphylococcus aureus was found alone; in 13 cases the staphylococcus albus was found alone; in 14 cases the two were found in conjunction; in 7 cases the staphylococcus aureus and the streptococcus were found; in 7 cases the staphylococcus albus and the streptococcus were found; in 2 cases the staphylococcus aureus and the pneumococcus were found; in 2 cases the staphylococcus aureus and a diplococcus were found; in 1 case the staphylococcus albus and the bacillus coli communis were found; in 1 case the staphylococcus aureus and albus and the streptococcus were found; in 1 case the staphylococcus aureus and albus, the streptococcus and the bacillus pyocyaneus; in 14 cases the streptococcus in pure cultures was found; in 3 cases the pneumococcus in pure cultures was found; and in 1 case the bacillus pyocyaneus in pure culture was found.

When Unna published his text-book in 1894 he believed that staphylococci were the cause of impetigo, and said that if we examined the interior of impetigo pustules we should find staphylococci. Now, after a lapse of five years Unna, in collaboration with Frau Schwenter-Trachsler, in a brilliant series of articles, has abandoned his former belief and claims that a special streptococcus is the pathogenetic factor. One point, however, is especially striking, and that is that he no longer searches for the cause in the primary, unbroken pustule, but in the characteristic, exuded, coagulated serum of the impetigo crusts. It is hardly fitting for a young writer to question the verdict of so experienced an authority as Unna, but I should certainly agree with the opinion of Crocker when he says "that search has been made in the crusts (for the cause of impetigo), but their liability to become contaminated is so great that no deductions can be drawn from such observations."

Unna differentiates his impetigo coccus from the streptococcus vulgaris by the following characteristics, which we see are quite unusual: "The chains are always short and composed of from four to six cocci; the chains are quite straight, or at most slightly curved; the chains never form loops or curves; the cocci are irregular and differently shaped; the cocci have their long diameters at different angles; the contents of the cocci often receive the stain unevenly; the colonies are thick and irregular, with several short, apparently broken off, branching twigs."

Thus, at too great expense of your patience, I fear, I have stated the bacteriological history of impetigo and its sister affections — sycosis, ecthyma, furunculosis, abscess and carbuncle, and I think it is fair to claim that the great majority of investigators concur in the opinion that they are all probably of staphylococcal origin. There have been a few notable exceptions where men have believed in the streptococcal theory, but to our way of thinking there have always been serious flaws in their arguments.

My own investigations relate to the examination of all pustular lesions which were presented at the skin clinic of the Massachusetts General Hospital between February 23d and April 13th of this year. The material for inoculation was in all cases taken from under the unbroken skin. In enumerating the diseases I shall divide them into the two groups which I have described above, and must explain the comparatively small numbers of impetigo and ecthyma by the fact that these studies were carried on during the cooler months when poor children play mostly at home with their arms and legs protected by clothing.

In the first group there were 11 cases of impetigo, 10 cases of sycosis, 14 of furunculosis and 2 of carbuncle. In the second group there were 39 cases of acne vulgaris, 11 of dermatitis, 4 of syphilis, 3 of ringworm, 2 of lupus vulgaris, 2 of herpes, 2 of scabies, 2 of impetiginous eczema, 3 of iodide of potash and 1 of bromide of potash dermatitis, 3 of dermatitis venenata, 1 of herpes zoster and 1 of tuberculous gumma — in other words, 111 examinations. From this number the staphylococcus pyogenes aureus or albus appeared 88 times, the bacillus subtilis 4 times, the micrococcus tetragenus 3 times, the streptococcus 4 times, a doubtful bacillus once and in 24 instances the tubes remained sterile. From 12 cases there were two different bacteria isolated and in 1 case three were found. Thus, excluding the sterile cases and the non-pyogenic organisms, we find that in the first division of diseases there were 36 infections from staphylococci and 1 from streptococci, while in the second division there were 45 from staphylococci and 3 from streptococci.

Therefore, these Boston figures lend themselves in a very striking manner to the theory of the staphylococcal origin of pustular affections of the skin, and to

emphasize my testimony more strikingly I append the following table:

FIRST DIVISION.

	Staphylococcus aureus.	Staphylococcus albus.	Streptococcus.	Sterile.	Uncertain.
Impetigo	7	3			
Sycosis	7	2			
Furuncle	9	2		2	
Carbuncle	2				

FIRST DIVISION (cases with double infection).

Impetigo	2	1	1	
Sycosis	1	1		
Furuncle	1	1		

SECOND DIVISION.

Acne	1	20		14	1
Dermatitis	4	2	1	1	
K. I. dermatitis				2	
K. Br. dermatitis				1	
Scabies	1	1			
Impetiginous eczema,	2				
Zoster		1			
Herpes				1	
Ringworm				1	
Syphilis		3			
Lupus vulgaris	1			1	
Dermatitis medicamentosa		1			
Dermatitis venenata	2				

SECOND DIVISION (cases with double infection).

Acne	2	2	
Dermatitis	2	1	
Scrofuloderma	1	1	
Herpes			1

And now in closing let me say a few words about impetigo contagiosa from a clinical standpoint. Etiologically I hope I have made it clear that the disease is in all probability due to the specific action of staphylococci, and in this connection I want to speak of its far greater prevalence in warm weather.

In the skin department of the Massachusetts General Hospital in 1897 there were 118 cases of this disease recorded; in 1898 there were 206 — a gain of almost 100 per cent. When we recall the two summers and the two autumns and contrast them one with the other, we shall remember that in 1898 we had an unusually severe summer heat which made itself felt almost into December, while in 1897 we had a comparatively cool summer and an average autumn. Now, if we look at the following table we shall see more strikingly how closely the figures correspond to the severity of the heat.

1897,	First quarter	21 cases.
"	Second quarter	14 "
"	Third quarter	51 "
"	Fourth quarter	32 "
1898,	First quarter	34 "
"	Second quarter	30 "
"	Third quarter	74 "
"	Fourth quarter	68 "

There is another etiological point which I wish to bring to your notice, and that is the presence of pediculi on the scalp. I have no direct figures to present in this connection, but you all have noted this coincidence in your practice among the poorer classes. I do not lay too much blame upon pediculi as direct agents in the genesis of impetigo, although I have stated above that Dewévre proved that the disease could be produced by rubbing pediculi from an impetiginous child upon the skin of a healthy child; but I do wish to emphasize the fact that by their presence a scratching of reflex origin is established which causes the child to inoculate himself with the staphylococci which surely abound under his finger nails. The presence of pediculi is therefore a condition upon which we must all strive to make war, and especially among school-children, where the disease is so prevalent. This crusade is now being carried on in the Boston public schools, and, I think, with success.

Another point is that in warm weather poor children play about the streets more than in the colder months, and these same children are apt to wear very little clothing when the heat is intense. Therefore, in summer and in autumn we see impetigo scattered over the whole body, and especially about the face, lower arms and hands, lower legs and feet; while in winter, except in babies, the disease is generally limited to the vicinity of the mouth, nose, ears and eyes.

As to the age at which impetigo contagiosa appears, it is safe to say that nine-tenths of the cases occur in childhood, but there are, however, instances of the affection in adults, and of this latter class I want to say a few words, as it is a condition not quite well enough understood by the general practitioner. In children the clinical picture is quite constant, and we are all well acquainted with the uneven, thin, moist, superficial crusts, varying in color from lemon yellow to orange, which appear, often in the midst of superficial, oozing excoriations upon the more exposed parts of an otherwise rather dirty child. When we come to the adult type, however, we meet a very different condition. Here we find that the subject is almost always a young man, and the seat of the lesions generally the shaven part of the face. We find very often an interesting succession of infections occurring in members of the immediate family or in the patient's intimate companions. The lesions are usually just below the horny layer of the skin and consist of broad, very shallow pustules extending about the shafts of the hair and covered with yellowish white scales. The progress of the disease is very rapid, and for this reason we are not apt to see isolated lesions, but irregular, gyrate groups covering a considerable area of one or both cheeks. This type is not associated with pediculi, and we seldom if ever find these animal parasites or any evidence of scratching, but we do inquire about the habits of the patient, and often learn that he is shaved at a barber's shop or uses a companion's towel. Here again, therefore, we must enter another plea for more careful cleanliness among both barbers and the public, and demand a more thorough disinfection of the implements and the utensils of the toilet, both public and private.

As to the treatment, there are only a few words to say. In the juvenile type plenty of soap and water at frequent intervals, an application twice daily of a five-per cent. boracic-acid ointment and a thorough soaking of the scalp with crude petroleum for three successive days will, within a week, destroy all active evidences of the disease. We must, however, often wait several weeks for the brilliant erythema, which underlays the crusts, to disappear. In the adult type, on the other hand, we must use rather stronger drugs and must expect a rather longer treatment before the activity of the process is checked. A five-per cent. ointment of sulphur, or the application of black wash for fifteen minutes night and morning in conjunction with a five-per-cent. ointment of salicylic acid and carbolized cosmoline, will usually prove sufficient to cope with the bacteriological invasion. Here again soap and water and clean towels, razors, combs and brushes are indispensable if we wish to be free for now and all time from impetigo contagiosa.

MULTIPLE ULCERS OF THE VULVA AND VAGINA IN TYPHOID FEVER.

BY AUGUST JEROME LARTIGAU, M.D.,

Assistant in Pathology and Bacteriology, Bender Hygienic Laboratory, Albany, New York.

PERHAPS no subject connected with typhoid fever has latterly excited so widespread a scientific interest as the bacteriologic relations of the bacillus typhosus to the complications and sequelæ of this malady. A whole series of diverse lesions in many organs and tissues have been described for which this specific organism has been held responsible; but, notwithstanding the not uncommon dissemination of Eberth's bacillus in the most remote and varied tissues, invasion of the female organs of generation is an accident of comparative infrequency. The disparate reports of gangrenous processes, abscesses, or other more or less extensive lesions involving the vulva and vagina have been collected by Keen,[1] but multiple ulcerations of the character described in the two cases reported herein are unknown to us in literature. In one case a bacteriologic study of the ulcerations was made and the typhoid organism found in almost a pure culture; in the second case no opportunity presented itself for similar investigation.

CASE I. Emily C., single, sixteen years of age, American, entered the Albany Hospital, April 3, 1898, complaining of headache, backache, and general malaise.

Family history. — The father is alive and well; the mother is dead, the cause unknown. One brother and one sister are alive and healthy.

Past history. — The patient cannot recall any past illness. Menstruation began at fourteen years, and has been normal.

Present sickness. — About two weeks ago she was taken sick with headache, pain in the back, and some fever. Several days afterwards pain developed in the left side of the vulva, which was accentuated on urination. On March 31st, two days after the appearance of the trouble in this region, a physician was called in and found a number of small superficial ulcerations on the labia majora and just within the vaginal orifice. From the beginning of her sickness until admission to the hospital the anorexia has been almost complete; bowels constipated.

On admission into the hospital the temperature taken in the mouth was 102.8° F.; pulse regular, of fair volume and 100 per minute; respirations 26. At this time the following note was made: Patient is a delicately built, fairly well-nourished girl; skin pale and moist; pupils normal; mucous membranes pale; conjunctivæ slightly suffused. Tongue covered on the dorsum in the middle with a thick brown fur; papillæ prominent. No edema. No glandular enlargements. The cardiac dulness is not increased; heart sounds normal, except the pulmonic, which is somewhat accentuated; lungs are normal. The splenic dulness is somewhat increased; spleen is just palpable on deep inspiration just below the costal border. The liver dulness is apparently normal. The abdomen is generally tender, more especially in the hypogastric region. No ileocecal gurgling. Examination of the genitals showed about ten or twelve very small superficial, round or less often oval, sharply defined ulcerations located on the cutaneous and mucous surfaces of the labia majora, labia minora, and just within the vaginal orifice and external to the hymen. The margins are clear cut, and the bases covered with a thin layer of thick, yellow, purulent material. These ulcerations vary in size from the largest ones, which have a diameter of one centimetre, to those measuring about three millimetres. They involve only the superficial layers of the skin. No discharge from the urethra or the vagina could be detected.

April 5th, 10 A. M. Complains of pain in ankles and left chest. The ankles are free from swelling, but tender to palpation. Lungs normal. Physical condition practically unaltered. Pulse 102, regular, fair volume, not dicrotic; highest evening temperature yesterday was 104.2° F. Ulcerations on genitals present a similar appearance to that when first seen. Cover-slips were made and several cultures taken from different ulcerating points.

April 7th, noon. Considerable pain in abdomen, which is tender and tympanitic. Temperature 105° F. this morning at 10 o'clock. Mind clear. Chest normal. Urine is normal in quantity, highly colored, and contains neither albumin nor sugar. Microscopic examination shows no casts.

April 12th, 11 A. M. Cultures taken on the 5th contain growths of the typhoid bacillus. Widal reaction is positive. Patient's condition improved. Vulvar ulcerations completely healed.

April 16th, 10.30 A. M. Abdomen tympanitic and tense; spleen easily palpable; pulse 98 and regular; temperature 102.8° F.

April 24th, noon. Heart sounds weak; lungs show nothing abnormal. Improvement continues.

May 2d, 11 A. M. The temperature has been normal for four days. Two cultures were taken from the urine on the 25th of April and the typhoid organism was isolated from one of the specimens.

[1] Keen: Sequelæ and Surgical Complications of Typhoid Fever, 1898.

From this convalescence has been rapid.

Bacteriological examination. — Two cover-slip preparations were made from two different ulcerations on the labia minora and stained with aniline gentian-violet. They both contain many bacilli of medium thickness and length, with rounded ends, morphologically similar in both specimens, which easily decolorize by Gram's method. Three cultures were made on agar-agar slants from three various ulcerating points and subsequently plated in agar-agar in the usual manner. All plates contained an abundant growth of discrete, round, pin-head or smaller, white, finely granular colonies with a regular outline. The colonies are all made up of bacilli similar in morphology to those in the cover-slips. In one plate a single, yellowish-white, round, pin-head-sized colony grew in addition to the other colonies. Further investigation showed this colony to be made up of cocci, frequently in pairs, not decolorizable by Gram's method and identified as the micrococcus subflavus (Flügge). Experimentally this organism showed no virulency whatsoever; two cubic centimetres of a thirty-hour bouillon culture introduced subcutaneously into the thigh of a full-grown rabbit produced neither local nor general effects; an intravenous inoculation of one cubic centimetre of a twenty-six-hour bouillon culture likewise produced no reaction.

The bacillus on slant agar grew as a fine, translucent, gray, moist growth, slightly elevated above the surface. Gelatine was not liquefied. Stab inoculations in glucose, lactose and saccharose agar produced no gas. Litmus milk was turned faintly pink but not coagulated. On potato the growth was moist, glistening and almost invisible. Bouillon and Dunham's solution became diffusely cloudy at the end of twenty-four to forty-eight hours. No indol reaction could be obtained in Dunham's peptone solution. Young bouillon cultures contain bacilli, actively motile, which when stained by Pitsfield's method show eight to fourteen flagella (petechial arrangement). The bacillus was repeatedly tested with known typhoid sera and a positive Widal reaction was in each instance obtained.

CASE II. Nellie C., twenty years of age, was admitted to the Albany Hospital, suffering with severe pain in the loins and some headache. She had been sick about two weeks. On admission the temperature was 103.4° F.; pulse 100, and dicrotic. The spleen was palpable. Rose spots were discovered two days after entrance; and the blood, which was tested on the sixth day, gave a well-marked Widal reaction. The subsequent course of the disease was that of a severe typhoid fever, which culminated in the death of the patient on the eighteenth day of her stay in the hospital.

On the second day the nurse called the attention of the house physician to the existence of a number of ulcerations on the vulva. Inspection of the genitals showed the presence of nine or ten small superficial ulcerative lesions varying in size from those having the diameter of a pea to two or three measuring fully one centimetre. Some were round; others irregularly oval; all were well defined, with sharply cut margins, and the bases were covered with a small quantity of yellow muco-pus. The superficial strata of skin appeared involved only. Unfortunately no bacteriologic study was made of the ulcerations.

With the knowledge of the existence of typhoid bacilli in the urine the probability of the manner of infection becomes obvious in the first patient, although the possibility of the origin from minute bacillary emboli should not be forgotten; the number of ulcerative points, however, is less coherent with that possibility than with the not unlikely urinary origin of infection.

In conclusion, we wish to express our gratitude to Drs. Samuel B. Ward and Howard Van Rensselaer of Albany, N. Y., for the opportunity to study and report these cases.

NOTE. — Since the preparation of this report Dr. Hennessy, of this city, tells me that he has met with similar ulcerations in a case of typhoid fever in which, however, no bacteriological study was made.

Medical Progress.

REPORT ON PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

AORTIC ANEURISM AS THE CAUSE OF HYPERTROPHY OF THE LEFT VENTRICLE.

CALVERT[1] says that as there has been considerable conflict of opinion on this subject, he thought it worth while to see what light the post-mortem records of St. Bartholomew's Hospital threw upon it. He found that of 124 cases of aneurism of the arch of the aorta, 68 showed no hypertrophy, while in 47 it could be perfectly explained by other causes and in nine it very probably could. Therefore, so far as these records are concerned, there was practically no evidence in favor of aortic aneurism being the cause of hypertrophy of the left ventricle.

In the discussion which followed, Dr. Lazarus-Barlow said that the records of St. George's Hospital for the last two years entirely bore out Dr. Calvert's conclusions, for of 13 cases, it was expressly noted in eight that there was no hypertrophy and in the five cases in which it was present it was accounted for by aortic regurgitation or granular kidney. These results are in line with what he had already stated in his "Manual of Pathology," that hypertrophy of the left ventricle would not be expected unless the case was complicated by the presence of a lesion of the aortic valve. He doubted whether atheroma of the aorta by itself would cause hypertrophy, except in the very rare cases where it gave rise to some stenosis, but arterial sclerosis affecting the smaller arterioles was a frequent cause.

TREATMENT OF ANEURISM WITH SUBCUTANEOUS INJECTIONS OF GELATINE.

In June of 1897 Lancereaux,[2] in collaboration with Paulesco, called attention to a new method of treatment which he had been led to try by the previously reported effects of gelatine injections in increasing the normal coagulability of the blood. He showed at that time a patient with large aneurism of the aortic arch cured by this method, and he has since presented another case of aortic and one of subclavian aneurism with equally good results.

This success has led him to make claims for the method which have not been entirely shared by certain of his *confrères*, who, while acknowledging the

[1] Lancet, January 14, 1899.
[2] Bull. de l'Acad. de Méd., 1897; Gaz. d. Hôp., 1898; La Sem. Méd., 1897 and 1898.

great possibilities of the measure and admitting the triumph of his cases, urge, on the basis of their own experience, the danger of fatal result from thrombosis in other localities than the one desired. In reply Lancereaux maintains that the clotting will take place only where the vessel wall has undergone change, that is the aneurismal sac, and in view of certain obvious errors he feels justified in calling in question their methods. His directions are as follows: The solution is made with four grammes of white gelatine in 200 cubic centimetres normal salt solution and sterilized at 120° centigrade. For injection a flask is fitted with a rubber stopper traversed by two glass tubes, one of which reaches to the bottom of the flask and externally is attached by a rubber tube to a needle of large calibre; the other glass tube is short and is connected with a bulb or Potain inspirator. After thorough sterilization of apparatus and site of injection (preferably the buttock), the needle is plunged deeply into the subcutaneous tissues and the injection should not take over quarter of an hour. There is little if any pain and no marked systemic reaction. The patient should be kept absolutely quiet for a time and palpation of the sac should be avoided. Injections, which may consist of 100 to 200 cubic centimetres, should be repeated every six to eight days until the sac is obliterated.

CHRONIC MEDIASTINITIS; INDURATIVE MEDIASTINO-PERICARDITIS.

Whipham,[3] on the occurrence of a case in his own service, was able to collect from the post-mortem records of St. George's Hospital only four cases in a period of fifty years; with these four he has tabulated eight others from different sources, and in addition makes an abstract of a report of 25 cases by Harris.[4] He excludes from his own list pericarditis occurring in children as a complication of rheumatism or other diseases, unless the inflammation involved other structures in the chest as well as the pericardium, and also those cases where the matting together of the thoracic viscera by fibrous tissue was the result of tuberculous pleurisy.

Perhaps the most striking thing to be gleaned from the analysis is the great lack of suggestive diagnostic symptoms or evident etiological factors, even in the cases where the pathological changes were very extensive. So far as definite conclusions can be reached, the following seem most important:

Age and sex. — The apparent preponderance of cases in adult life is probably due to the natural chronicity of the disease, death not occurring until after a lapse of years. The proportion of males to females is four to one.

Causation. — Rheumatism is not an important factor, nor does any antecedent disease seem particularly to predispose to the condition. Tuberculous conditions may or may not coexist. The concurrence of chronic peritonitis with ascites is noticeably frequent.

Heart. — Hypertrophy of the heart is not a necessary result: in only 11 of 36 cases is enlargement noted; there may be extensive mediastinal changes while the heart remains normal or even diminished in size as result of contraction of adhesions.

Pericardium. — In the majority of cases the cavity is either partially or entirely obliterated by fibrous adhesions.

[3] Lancet, April, 1899.
[4] Medical Chronicle for 1895.

Pulse. — The rate is almost invariably accelerated, and in the majority of cases has been 100 or over. Pulsus paradoxus occurred in only nine of the cases included in the report, and in 50 per cent. of the cases in which it was observed no constriction of the large vessels by fibrous growth existed.

Diagnosis. — Especial attention is called to the difficulty of making a diagnosis and the plausibility with which the physical signs might be explained as depending on other conditions. The following are given as significant: puffiness of the face, cyanosis of the lips, edema of the thoracic walls, prominence of the veins of the arms and neck, and ascites.

Treatment. — From the nature of the process it is evident that, even with diagnosis established, there is little other than symptomatic indication for treatment.

LATENT AND EPHEMERAL PERICARDIAL EFFUSION.

Ewart[5] makes valuable addition to papers already published by himself[6] on recognition of pericardial effusions.

The first paper dealt with the value of certain diagnostic signs to which he attaches great importance but which have not been implicitly accepted by other observers; for example, the posterior pericardial patch of dulness; the first rib sign; the posterior patch of tubular breathing; tubular breathing below right mamma, etc.

In the other two communications he draws attention to an interesting condition which he is lead to believe exists much more frequently than is suspected by most clinicians (himself until lately included), namely, a pericardial effusion of small amount and brief duration, occurring "independently of acute inflammations, most commonly under the influence of rheumatism, of Bright's disease, and of valvular affections." He reports half a dozen illustrative cases where the condition might easily have escaped any but the most careful examination (the value of actual tracings noting results of percussion and auscultations, taken as a daily serial for comparison, is emphasized), and in conclusion makes the following summary: Pericardial effusion occurring as above noted may last not more than one to three days, after which complete absorption takes place. Owing to its moderate size and to the absence of the painful symptoms of pericarditis, and of the worst pressure symptoms, the effusion seems to be commonly overlooked. The dulness due to it is apt to be mistaken for an increased area of cardiac dulness and usually for cardiac dilatation. The pathological etiology of these effusions is not clear. They may arise from some acute inflammatory process, or more commonly, perhaps, they are passive, that is, dependent on some temporary alteration of the general or of the lymphatic circulation. Their spontaneous recovery in most cases shows that no special treatment is necessary. Re-absorption would obviously be hastened by diaphoretics, diuretics and cathartics.

(To be continued.)

[5] Trans. Clin. Soc., Lond., 1897.
[6] Brit. Med. Jour. and Lancet, 1896.

SPREAD OF PLAGUE. — Plague is reported to have appeared at Alexandria, in Egypt, and fourteen cases with two deaths have been reported. It has also broken out in Bushire in the Persian Gulf.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, Monday, May 8, 1899, DR. R. H. FITZ in the chair.

DR. J. J. THOMAS reported

TWO CASES OF INJURY OF THE CORD RESULTING FROM FRACTURE OF THE SPINE.[1]

DR. KNAPP: I think Dr. Thomas has put very well the diagnostic points between a fairly complete crush of the cord and a partial injury. There is one symptom which has impressed me occasionally in fractures in the lower part of the spine; that is a rapidly developing tympanites which is indicative, I think, of a complete crush of the cord. Not very long ago I saw a young woman who had rolled out of a window some twenty or twenty-five feet high, coming down upon the railing of a piazza and striking upon the lower portion of the spine. She at once had complete paraplegia, loss of sensation, paralysis of the bladder and rectum, and within a very few hours this marked tympanites had also developed. Spinal surgery was resorted to, although I felt at the time that it was entirely hopeless. The result was that the operation was useless, for there was a complete crush of the cord. Supposing we diagnose between a complete crush and partial injury, even then the promise of spinal surgery is on the whole slight, for, as a rule, if the cord is only partly crushed, operation will not help. Last year I saw a case which Dr. Graeme Hammond showed at the meeting of the Neurological Association in New York, which I supposed was the best result yet obtained by spinal surgery. The patient was a wrestler, who in wrestling had received a fracture of the cervical vertebræ, and for two or three weeks had been completely paralyzed. After an operation he made a complete recovery so that he resumed wrestling and was able among other things to do the bridge, in which he supported himself on the hands and feet on the ground with the back downward, holding himself so that the opposing wrestler could not force his shoulders down upon the floor. Theoretically we can imagine cases where spinal surgery may do some good — cases of extra-medullary hemorrhage and cases where the vertebræ have been broken with such extreme delicacy that the fragment comes down just so as to touch the cord and to press upon it enough to cut off conduction, but not enough to injure the delicate substance of the cord itself. Those cases are theoretical; they can be conceived, but practically it must be an exceedingly difficult process to exert the violence in such a way as to break the vertebræ without doing more harm to the cord; the ordinary rule, of course, being that the fragment is rapidly and forcibly driven upon the cord and springs back again into place, causing an immediate crush and not a long-continued pressure. That I think Dr. Thomas has shown very clearly in the cases which he has reported.

The explanation of the question of the knee-jerk is certainly puzzling. Brissaud has recently gone over the subject, and has laid considerable stress upon the point which Dr. Thomas has brought up, as to the possibility of injury either to the anterior horns, or to the cells of the anterior horns, or to the nerve trunks or nerve roots. In a very large number of these cases of injury in the cervical region the patient does not live long enough, even if his death is not aided by spinal surgery, for us to discover whether the knee-jerk may or may not eventually return. A good many years ago I was inclined to believe that irritation in the upper portion of the pyramidal tract might cause for a time a loss of knee-jerk. I remember in particular one case of a negro, whom I think Dr. Webber may possibly remember in his service at the City Hospital, with a syphilitic history, who had, I believe, a sudden paraplegia coming on during coitus. He had all the symptoms of a transverse myelitis, with a complete loss of knee-jerk. It was before the days of reinforcement, but under the ordinary conditions the knee-jerk could not be obtained. With that there was complete paraplegia, complete anesthesia, and paralysis of the bladder and rectum, but after he had gone on for a number of weeks in that condition the knee-jerk returned and there was a marked exaggeration, with clonus. Whether in these cervical cases, where there is a pretty complete crush, the knee-jerk may return at the end of six or eight weeks is still uncertain, because, as a rule, too few of the cases live for us to determine that point; although one case of absolute division of the cord which I remember, where there had been laminectomy, and the two ends of the cord were seen absolutely divided in the spinal canal in the upper or mid-dorsal region, there was a complete absence of knee-jerk about a year after.

DR. WEBBER: I remember the case that Dr. Knapp referred to at the City Hospital, and another curious point in regard to it was that the coitus was in the standing position, and I remember seeing it stated that coitus in the standing position might cause myelitis. I do not remember any more of the particulars of the case than Dr. Knapp has spoken of, only I had an impression that the symptoms were not absolutely sudden, as in the case of injury or hemorrhage, but that some hours were occupied in the development of them. It is possible there may have been one or more very minute hemorrhages at the starting point for the myelitis.

In regard to Dr. Thomas's paper I have been very much interested in the paper, and each point that I thought of speaking of as he read he fully covered in his discussion of the subject, so that I have nothing further to add. I was very much interested in his discussion of the knee-jerk, and the paper I think is a very instructive one in regard to the fact that in a great many of these cases there is no pressure on the cord. That point I think he has well brought out, and where there is crushing, the bones spring back into place and the canal is sufficiently clear for the normal cord to pass through without being pressed upon. Another point I thought was interesting was the small amount of hemorrhage which was found around the cord and perhaps the small amount in the cord itself. I have only seen a few cases of fracture. Recently I have not seen any, not being connected with a hospital, but in the few cases I have seen I do not remember any where the symptoms were such as to give any hope of improvement from operation. I think all the cases I have seen died,

[1] See page 233 of the Journal.

and the result appeared to be inevitable from the very beginning of the injury or when I first saw them.

Dr. Scudder: In the cases I have looked over recently I find that the weight of evidence is against surgical interference in these cases unless there is some definite lesion of the laminæ of the vertebræ. I have seen recently the microscopic sections made from two cases that were operated upon by laminectomy at the Massachusetts General Hospital (the sections were made by Dr. Taylor), in which I was very much struck by the fact that the dura was intact throughout the whole circumference of the cord. The microscopic findings in these cases have been described by Drs. Taylor and Lord in a report of the Boston Society of Medical Sciences.

I was also struck by the fact that in these cases the lesion of the cord was confined to the anterior surface of the cord, so that the surgeon upon removing the laminæ would detect no hemorrhage outside the dura, and would obtain no information as to the damage done. Moreover, could he have seen the anterior surface of the cord he could have done nothing to relieve the conditions present.

There is one surgical procedure that ought to be emphasized in this connection, and that is the immediate rectification of the deformity and the maintaining of the corrected position by plaster-of-Paris splint. Dr. Burrell ten or twelve years ago went over the cases at the City Hospital with reference to this method of treatment and its results, and he found that there is a certain number of cases with a distinct kyphos at the seat of the lesion, in which, by immediately correcting the deformity and holding it corrected, the symptoms have disappeared and the patients in a certain number of cases have recovered. Of course the number is few that have recovered. The procedure is, however, justifiable and is warranted by the facts.

Dr. Thomas: I will say in regard to Dr. Scudder's remarks, that I meant to include not the application of plaster-of-Paris, but extension when I spoke of replacement by hyperextension; and, of course, fixation should follow this, either by immobilizing the patient in bed by bags of sand, or by some other means. I think few surgeons would now advocate suspending the patient, because of the risk of injury in moving him about as much as that when practically the same results can be obtained upon a hammock by hyperextension or some such method as that.

Dr. J. L. Morse read a paper entitled

RENAL COMPLICATIONS OF THE ACUTE ENTERIC DISEASES OF CHILDHOOD.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held at the Academy of Medicine, in New York City, May 9, 10 and 11, 1899.

(Concluded from No. 9, p. 221.)

Dr. Abraham Jacobi, of New York, read a paper on

FUNCTIONAL CARDIAC MURMURS.

From his observations of heart disease in children, who as a rule present a simpler problem than when we have to deal with the disturbing elements of adult age, Dr. Jacobi is convinced that real functional heart murmurs, murmurs due to faulty action of the valves or muscle without pathological change in the organ, are much rarer than formerly supposed. Recent studies of the myocardium show that its changes may sometimes give rise to murmurs. When the child's heart is developing the cavities enlarge, but the wall of the heart does not always grow thicker. During this period murmurs may be heard and they would appear to be due to myocardial insufficiency at certain times, constituting an organic, not functional, defect.

Dr. Howard S. Anders, of Philadelphia: I think Dr. Jacobi's paper and experience certainly has a tendency to clear the atmosphere. So far as my experience goes it has led me to the belief that the term "functional cardiac disease" can be largely done away with. Functional cardiac disease usually means relative insufficiency of one of the heart orifices; or if it means anemia we certainly have no reason to call it functional. If it is due to myocardial disease, or if there is an alteration in the constituents of the blood, the murmur is certainly not functional, but organic. It is far more accurate to call these diseases organic.

Dr. John C. Munro, of Boston: I hesitate to say anything in contradiction to what Dr. Jacobi said, but three years ago, in my surgical wards at the Boston City Hospital, I had the patients examined very carefully immediately preceding and following operation, regardless of the nature of the operation. Upon summing up our results, we found that a fair proportion of the cases — I cannot remember the exact figures — had a marked functional murmur (so-called) at the apex and base, with an accentuated pulmonic second sound during the period just preceding the operation, but within two or three days after the operation the murmurs disappeared. This was especially noted in women of the shop-girl class, in whom a murmur would rapidly appear when the operation was imminent, and disappear as rapidly if the operation was postponed or after its performance.

Dr. Harold Williams: It is customary to speak of those so called function murmurs as hemic and dynamic. There is no sufficient reason to believe that hemic murmurs really exist. Dynamic murmurs are, literally speaking, organic. This entire subject has excited much discussion. Dr. Prince, of Boston, examined many applicants for appointments as firemen and policemen and found that those who were very apprehensive suffered from a tumultuous action of the heart and had systolic murmurs which corresponded with all the requirements of regurgitant mitral murmurs. They were functional murmurs, due to interference with the function of the heart, and rapidly disappearing. He accounted for them by over-contraction of the left ventricle forcing the muscular mitral valve.

I have been struck by the presence of these functional murmurs in overtaxed hearts where the exact converse existed to what Dr. Prince found, namely, a too feeble contraction of the mitral valve. This too feeble contraction causes incomplete closure of the valve cusp and is consequently followed by mitral regurgitation. Thus it would seem that the so-called functional murmurs are really organic in that they are due to a temporary derangement of the organ. In the same way "organic murmurs" are functional in that their origin is a functional disturbance due to organic defect. It is therefore a question of nomenclature.

DR. JACOBI: There undoubtedly are functional murmurs, and those alluded to by one of the speakers as occurring before operation and some of the others mentioned are certainly of that nature. There are functional murmurs of other kinds. For instance, now and then in severe cases of chorea you will get a heart murmur for a day or two, which then disappears only, perhaps, to appear and disappear again later, and such a changeable murmur is certainly functional. The fact should be borne in mind that murmurs produced in veins have been mistaken for heart murmurs. West, eminent though he was, frequently made that mistake. As far as so-called hemic murmurs are concerned, which are attributed directly to anemia, I do not believe that they exist. Even in pernicious anemia or in infantile scurvy no such murmur may exist. This would prove that anemia by itself does not produce such a murmur, but when the anemia is of long standing and has affected the structure of the tissues, we may have a murmur which is the result of malnutrition of the tissues of the heart and of the blood-vessels. We cannot expect to find a hemorrhage from the blood-vessels, no matter what the condition of the blood may be, unless there is an abnormal condition of the vessels themselves. When the blood-vessels become undernourished by the condition of the blood, then there will be a hemorrhage. Something similar I think is the relation between anemia and functional heart murmurs.

DR. L. D. JUDD, of Philadelphia, read a paper on

HYGIENICS OF THE SKIN.[1]

DR. L. D. BULKLEY: Dr. Judd has certainly brought out this subject well. His views, however, as based upon his experience, are so diametrically opposed to mine that I hardly know what to say. For many years both summer and winter, I have been wearing underclothing of Scotch wool next to the skin, and I have certainly derived more comfort and benefit from it than from cotton underclothing.

I also differ from the doctor somewhat in regard to the amount of bathing. As a young man I was very enthusiastic about the value and necessity of the daily bath, but after I had been practising medicine for some ten years, I read a paper by Hebra, my master in Vienna, in which he discountenanced the too free application of water to the skin, and showed that it was those who bathed most who suffered the most from skin diseases. My own experience since then has taught me that the two free use of water to the skin does harm rather than good.

DR. C. C. RANSOM: Dr. Bulkley has perhaps overlooked the fact that the majority of the patients he sees are suffering from skin diseases. I do not think there is any real connection between frequent bathing and the production of skin diseases. The Turkish bath attendant is often in the bath for hours, and he usually has a beautiful skin. Weakness from bathing I believe is due to the fact that the bath is unwisely taken.

DR. W. DUFFIELD ROBINSON, of Philadelphia, read a paper on the

CLIMATOLOGY OF NUDITY,

dealing with the subjects of light, heat and atmosphere. The author noted the neglect of light in medical climatology and the tendency to lay stress much more largely on air. In a previous paper Dr. Robinson showed to the Association the penetration of various fabrics by light. The author introduced his subject by considering the physics of light, its absorption by the body. He suggested that the rash, the blood engorgement of the skin, in measles, scarlet fever and erysipelas is nature's effort toward securing light, energy and effective oxygen compounds in the blood in the greatest quantities. Dr. Robinson suggests that quinine in solution, as it must be in the blood, absorbs ultra violet and violet waves of light, and speedily emits them in colors, fluorescence, and asks: Can quinine, carrying light, thus bring death to the malarial plasmodium and destruction to its toxins? As bearing on the power of the nude human skin to absorb all kinds of light waves, the successful photographing has been reported in absolute darkness of a nude subject just after he has been very freely exposed to a copious bath of strong sunlight. Photographers have to keep glass intended for coating for negatives in absolute darkness for long periods to insure the escape of absorbed actinic waves. Lupus has been cured by concentrated sunlight. Dr. Robinson contended that the x-rays are not a form of light; that true burns cannot be produced by them and that they are not bactericidal.

DR. W. F. R. PHILLIPS, of the Weather Bureau: I believe that in the future study of climatology greater advances will be made in the study of light than in the study of barometrical pressure. The two factors which we should study carefully in connection with climatology are heat and light, those two forms of energy which our organism appreciates most keenly, and which it can be demonstrated are effective upon us. It seems strange that the effect of light upon the organism has not been noted earlier, because even in the very oldest physiologies the statement is made that animals in the light absorb much more oxygen than they do in the dark; that hibernating animals, even when taken out of their abode while asleep, would absorb more oxygen than before they were taken out. Experiments upon human beings have shown the same thing. In the early seventies, when the fact was brought out that light was a bactericidal agent, attention was also called to the fact that oxygen and ozone, which are powerful oxidizing agents, were perfectly powerless in the dark. They must be exposed to light; otherwise they are perfectly inert. The early experimenters were of the opinion that exposure to light did not alter the chemical composition of fluids in which germs might be growing, but I think subsequent investigators have proven very conclusively that the exposure of a culture medium to light does so profoundly alter an ordinary medium that the germ which occupies it is no longer able to be active.

DR. SOLLY: I am fully convinced of the value of light and its powerful influence in climate, and perhaps when one is considering the subject of high climate, it is one of the most important factors. Dr. Weber recognized this years ago, as well as many others. We must investigate these factors side by side, and we want to get facts about the different points, and not jump to the conclusion, because a man writes a paper on one part of a subject, that he means to limit his belief to that factor only, whether it be diminished barometic pressure, or heat, or light, or humidity, or what not. These factors are closely interwoven, and it is only by taking each one singly

[1] See No. 5, page 104 of the Journal.

that we can disentangle the meshes. I do not refer to the meshes to which Dr. Judd called our attention yesterday.

DR. WM. M. GIBSON, of Utica, presented a paper on

THE BEARING OF EMBOLISM ON THE COURSE OF VALVULAR HEART DISEASE.

After general consideration of mitral disease, cerebral and pulmonary embolism and venous thrombosis, the author cited a case of cystic kidney and accompanying inflammatory tissue having origin by embolism from endocardial inflammation; also a case of mitral regurgitation in which an area of skin on the left thigh and the outer surface of the right leg showed small infarctions and a low state of nutrition bordering on gangrene for weeks. The tax suddenly thrown on compensation by the occurrence of gangrene is very liable to produce extreme dilatation even if the patient rallies against the general effects of septicemia.

Dr. Gibson cited a case of mitral stenosis of long standing in which sudden gangrene of the right foot and leg developed after an attack of influenza and right lobar pneumonia. Amputation above the knee arrested the gangrene and the stump healed kindly; but a recurrence of pneumonia, probably embolic, proved too much for the patient's strength. An examination of the amputated leg disclosed an organized clot nearly two inches long at the bifurcation of the popliteal artery. Dr. Gibson also furnished the history of a remarkable case of embolism of the mesenteric artery following fracture of the humerus caused by a fall from a bicycle. The patient was a man seventy years old, who had had several attacks of acute rheumatism in a period of thirty years, but had escaped endocardial disease until the winter previous to his injury. An exploratory laparotomy revealed a gangrenous fold of intestine due to embolism, which had occurred with violent symptoms on the day following the injury. Death occurred on the third day.

DR. H. L. ELSNER, of Syracuse, read a paper on

THE CARDIAC ASTHENIA OF PNEUMONIA.

The author believes that too much attention has been directed to the heart alone, disregarding entirely the condition of the peripheral vessels, particularly the arteries. Taking up the various drugs the author believes that the indiscriminate use of nitroglycerin is a growing evil with the profession in this country, especially as applied in cases of pneumonia. The writer has seen patients treated with some of the numerous cardiac tonic tablets now found in profusion on the market, all of them containing digitalis with nitroglycerin and a variety of other so-called heart tonics, and exhibiting the most alarming cardiac and respiratory insufficiencies, with rapidly lowering arterial tension. Dr. Elsner cautioned against the use of veratrum viride, but advocated strychnia and digitalis.

Dr. Elsner's method consists in administering every fifteen minutes fifteen drops each of the compound spirit of ammonia, the compound spirit of lavender and the tincture of valerian. This is kept up day and night until the pulse shows improved tone and the heart action is decidedly better. Valerian may be omitted if not retained and whiskey or brandy substituted. Spartein sulphate in quarter-grain doses with four to six grains of caffein are given every two, three or four hours. Tokay wine was recommended. Dr. Elsner was doubtful about the value of oxygen and considered its usefulness as yet unsettled.

DR. WALKER: I have had such satisfactory results with nitroglycerin in pneumonia, first using it at the suggestion of Dr. Da Costa, that I wish to say a word in its defence. In my experience it has benefited these patients more than all the ammoniacal stimulants. I remember a very severe case of pneumonia which I saw about two years ago. The patient was a boy. I gave him one one-hundredth of a grain of nitroglycerin every two hours for at least two weeks with nothing but beneficial results. I recall another case, a lady who came to Philadelphia from Winchester. During her visit she developed pneumonia and her physician said she could not possibly recover. Under the use of nitroglycerin, however, the heart improved and the patient made a good recovery

I wish to mention another therapeutic agent which I have found of great service in cardiac asthenia, and that is dry cupping. My patients are dry cupped as long as the engorgement persists and whenever new pains occur.

DR. CURTIN: Nitroglycerin loses its effect in about three hours. In order to have a continuous effect, the dose should be repeated every two or three hours.

DR. JUDSON DALAND: I recently had an opportunity to make some experiments with digitalin on an individual who was in normal health, with the exception of a slight bronchitis. I increased the dose of digitalin (Merck's) until the patient was taking one-quarter of a grain every four hours, and the drug produced almost no effect.

DR. BABCOCK: I have no doubt that theoretically Dr. Elsner's treatment is successful and practically he has accomplished what he wished to. But we have all seen cases of pneumonia with paresis of the capillaries, in which nitroglycerin has been of the greatest benefit. It depends on the way in which it is used. As pointed out in the admirable paper of Dr. H. C. Wood about a year ago, nitroglycerin, in doses of one one-hundredth of a grain, placed on the tongue, is a very valuable heart stimulant, whereas larger doses will do harm. In larger does it is a cardiac paralyzant, while in small doses it indirectly stimulates the heart's action. In these cases of capillary paresis we have all seen the benefit of digitalis, strychnia and nitroglycerin, but not until the latter has been added.

DR. JACOBI: Digitalin, which I first tried many years ago, I regard as a useless product.

DR. ELSNER: I expected, in presenting this paper, to meet with adherents of the nitroglycerin treatment. I dare say that in the majority of the cases which are cited the nitroglycerin was given in connection with other remedies which we know are effective heart stimulants, that is, strychnia and digitalis.

DR. L. D. JUDD, of Philadelphia, presented a paper entitled

REMARKS BASED UPON A FURTHER EXPERIENCE OF THE USE OF CALOMEL IN DIPHTHERIA.

DR. HAROLD WILLIAMS, of Boston, read a paper entitled

THE EFFECTS OF VIOLENT AND PROLONGED MUSCULAR EXERCISE UPON THE HEART.

His paper consists of the report of examinations held upon long-distance runners and of a study based thereon of the effects of such violent and prolonged exercise upon the heart. The paper includes preliminary studies made upon athletes immediately before and after long practice runs, and a detailed study of

the results of an examination recently held upon Marathon runners. In this examination records were made of the weight, pulse, temperature, respirations, urine and heart, before and after the race. The significance of heart murmurs heard in the second left intercostal space and their diagnostic value are discussed at some length. The conclusions arrived at are: The fallacy of general statements made in regard to the effects of exercise upon the heart; the importance that every heart and every form of exercise should receive special consideration; and that the effect upon the heart of such long-distance running as is described in the paper is chiefly to be regarded as a participation of the muscular stricture of the left ventricle and its muscular mitral valve in the resulting general muscular exhaustion.

One of the runners in this contest presented some very interesting features. After a practice run of five miles he showed a temperature of 98°, pulse 100, respiration 32, a faint trace of albumin and a sphygmographic tracing of high arterial tension. After the twenty-five-mile race he showed a loss of 4.9° in temperature and four and a half pounds in weight, respiration 24, one tenth per cent. of albumin with numerous casts, and a pulse of 104 and of exceedingly low tension. All the runners showed an extreme condition of general muscular exhaustion. A significant fact was that those who won first and second place had no murmurs, while others had murmurs after the race. The greater the muscular vigor the less the liability to murmur.

DR. JOHN C. MUNRO, of Boston, read a paper on

EMPYEMA FROM A SURGICAL STANDPOINT.

In the first place, he advocated the use of ether as an anesthetic, although he used chloroform in double empyema in children where struggling and coughing must be reduced to a minimum. The author has had delayed expansion or incomplete permanent expansion in both pneumococcic and streptococcic empyemata, but where the operation has been done soon after the formation of pus immediate expansion has taken place in both types, although, as a rule, complete expansion is more likely to be slower in the pneumococcic cases, that is, full resonance is not noted before several weeks. The deaths in Dr. Munro's cases have come from embolus from hearts displaced by a left pleural cavity filled with pus; from a relapse or an extension of a pneumonia, and in the streptococcic cases from a rapid general infection. The latter cases are occasionally so rapidly fatal that no matter how early the cavity is emptied nothing is of avail.

DR. V. Y. BOWDITCH: I agree with the reader of the paper so thoroughly that I have little or nothing to add. It has always been my custom to refer the case to a surgeon for operation at once if pus is found in the pleural cavity, unless it be a case of pyopneumothorax in conjunction with advanced phthisis, in which case I question whether a permanent opening is advisable from the fact that it is merely an additional source of discomfort to a hopelessly ill patient and occasional aspiration may be sufficient to relieve urgent symptoms. With regard to the use of the pneumatic cabinet, I have had no experience with it in empyema, but it suggests itself as a valuable adjunct in the expansion of the lung. I should like to hear from those who differ from Dr. Munro about the advisability of immediately operating when pus is found.

DR. HAROLD WILLIAMS suggested that perhaps the unfavorable results which have been reported were due to the manner in which the anesthetic was given rather than to the anesthetic itself.

DR. HOWARD S. ANDERS read a paper on

THE RELATION OF LOCAL METEOROLOGICAL CONDITIONS TO THE INFLUENZA EPIDEMIC IN PHILADELPHIA IN THE WINTER OF 1898–1899.

He has made a careful study of the atmospheric pressure, mean monthly temperature, maxima and minima, the mean daily range and mean variability, the relative humidity, the precipitation, the prevailing direction, total movement and velocity of the wind and the general weather conditions during the months of October, November, December and January for the years 1895 to 1899 inclusive. Dr. Anders shows that during November and December, 1898, there were several volleys of attack, as it were, in which influenza suddenly overcame numbers of people for three or four days or a week and then seemed to subside to a degree to be followed by other exacerbations and remissions of invasion; these attacking periods were invariably preceded by sudden thaws, thick ill-smelling fogs and relatively warm, moist and calm weather; they were apparently introduced by cold, clear, dry and windy weather. These changes appeared to be unusually sudden, extreme, frequent and rapid. Fogs were noted. The conclusions are still uncertain.

DR. GUY HISNDALE, of Philadelphia, read a paper on

THE COLD WAVE OF FEBRUARY.

After tracing the meteorological conditions leading up to this cold wave, which was a continuation of three distinct waves, he showed the effect on the community in the loss of life by which 104 persons perished between January 29th and February 13th. Twenty-four of these died in Colorado by freezing and by avalanche; in Texas 15; in Pennsylvania 11, and in New York 10. The hardships from scant food and fuel supply were more widespread than in any other cold wave of which we have records in this country.

The new record established for Washington was — 15°, — 7° at Baltimore and — 6° for Philadelphia.

The snowfall in Philadelphia began on February 11th at 9 P. M., and continued until the 14th at 1 A. M., during which time 18.60 inches fell. The wind was from the northeast and blew at times at the rate of sixty miles an hour. The lowest barometer was 29.92 inches. The estimated monetary loss in Philadelphia was $2,500,000, and in the country at large $20,000,000. Food rose in price and there was a shortage in meat, coal, milk, fresh vegetables, oysters, fish and flour. The financial loss was incalculable.

One of the most remarkable phenomena was the flow of ice down the Mississippi River on the 17th of February past New Orleans and into the Gulf of Mexico, an event never before witnessed during the memory of man. Ice an inch thick formed at the mouth of the Mississippi, in East and Garden Island Bays and the temperature fell to 10° on the 13th. Another phenomenon was the fall of snow at Jacksonville, Florida.

DR. R. G. CURTIN, of Philadelphia, read a paper on

CARDIO-ESOPHAGEAL GUSH AND CLICK SIMULATING A HEART MURMUR.

The author believes them to be extrapericardial, esophageal. They are synchronous with the action of the heart and as far as the author knows, not heretofore described. In one case the sound was more distinctly heard when the ear was held in front of the open mouth than when applied to the chest. It sounded like a short gush of air from the throat modified by the upper air passages giving it a low-pitched, grunting sound. The sound continued while the patient was talking and breathing. In some of the other cases the sound could be heard across the room or further.

DR. E. O. OTIS, of Boston, read a paper entitled

NOTES ON TUBERCULIN TEST.

DR. LANGMAID: In the early days of tuberculin I saw a striking example of the injurious effects following its injection. Unknown to me, five or six patients in my service at the Massachusetts General Hospital were injected with the remedy, and shortly afterwards in passing through the ward, I noticed that something was amiss with the larynges of those patients. I had never before seen a larynx in such a terrible condition. My assistant then informed me that he had been induced to allow the injection of tuberculin to be made in a number of my patients. I therefore immediately forbade its further use in my clinic. Since then, of course, the tuberculin has been much modified.

I would like to ask Dr. Otis what the outcome was in the cases of cervical adentitis in which the tuberculin was used? Did the patients show any subsequent evidences of tuberculosis in the bones or in any other tissues of the body? Suppose he does get the evidences of tuberculosis in these cases of cervical adenitis, what does he expect the future course of such patients will be? What will be the outcome of these tubercular patients?

DR. OTIS: The primary object of this series of observations was in order to determine, if possible, what proportion of cases of enlarged glands in the neck were tuberculous in character. The only one I could find who had investigated this subject was Valland, and his evidence seemed to me unsatisfactory. The result of the injections in the various cases indicated in a measure the treatment. Valland and others are of the opinion that tuberculosis which manifests itself at first as a cervical adentitis frequently goes on to pulmonary tuberculosis.

The injections were made principally on hospital patients and were not objected to and no bad results followed.

QUININE IN THE UNITED STATES ARMY. — We learn from the *Medical News* that more than 125,000,000 grains of quinine have been taken by United States soldiers during the past year. It is said that some of the military patients in the army hospitals in Cuba and Puerto Rico took as much as 300 grains a week during several weeks. Hardly any of those who were in service in the West India Islands failed to take some quinine during their stay. A military correspondent writing from Puerto Rico recently said that practically none of the soldiers had been entirely exempt from malarial disturbances on that island and that while the malaria was usually not severe it was very obstinate.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 7, 1899.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

283 WASHINGTON STREET, BOSTON, MASS.

PROPHYLAXIS AGAINST SMALL-POX.

WITH the continued prevalence of sporadic cases of small-pox, particularly in view of approaching colder weather, it would seem that every possible measure should be taken to prevent its spread. The power to accomplish this end lies largely with the boards of health of the several States, who should certainly have the warmest support of the people at large. That such support is usually lukewarm until actual danger threatens we know too well, but the importance of the matter evidently demands that all legitimate means should be taken to instruct the people, without alarming them unduly, in regard to the nature of the disease and methods of its prevention, beyond the mere fact of vaccination.

We are glad to call attention, in this connection, to an excellent circular printed and distributed by the State Board of Health of Indiana, which is calculated to do much good in the way of educating the masses of the people in matters about which they are more than likely to gain erroneous opinions from the daily press. The circular of four rather finely printed pages is addressed to the people of Indiana, and is headed "Small-pox and its Prevention." The language is direct and simple and calculated to attract the attention of any one into whose hands it may come. It is stated that the disease has already appeared in twenty-six counties of the State, with a total number of nearly three hundred cases, of which, however, only four have thus far been fatal. The fear is expressed that with the coming of cold weather the disease will assume a more virulent form, and vaccination is urged before this possibility becomes a fact. The circular then goes on to state that if properly done there is no danger in vaccination, and describes briefly the process of vaccination, and the nature of the lesion resulting when it is successful, with the general causes of sepsis from careless after-treatment. All this seems to us an admirable method of winning the confidence of those who need vaccination, and whose minds are sure to be distorted by the folly of the antivaccination fanatics.

Following this is a statement as to the differential diagnosis of small-pox, warning against the possibility of mistaking it for chicken-pox. The lesions are described in perfectly simple language and their peculiarities insisted upon, with the added warning that it is safer to err on the side of over-caution in a matter of so much importance to the health of the community.

The remainder of the circular is taken up with directions regarding isolation, care of the sick-room, disinfection and, finally, by an address, put in concise form, to the public by the Indiana State Medical Society, upon the prevention of tuberculosis and small-pox. Regarding small-pox, the Society makes the following appeal:

"That the ordinary sanitary measures thoroughly applied, though of the highest value and by no means to be neglected, have nevertheless not proven sufficient to control the spread of small-pox; that in vaccination and revaccination accurately and thoroughly applied there is an almost absolute preventive of small-pox; that though with the lapse of years after successful vaccination the protective influence may decline and small-pox may be contracted, the disease is robbed of most of its dangers; that properly applied, in the hands and throughout under the direction of competent physicians, vaccination is attended with but insignificant risks, the disease-preventing and death-preventing effects vastly outweighing such risks; that upon the basis of these convictions, the State Medical Society does invite and urge the public to a full confidence in the preventive value of vaccination against small-pox, and does urge the public to relax in no direction its vigilance in the carrying out of this disease-preventing and life-saving measure."

This action of the Indiana Board of Health should be followed by other States in which small-pox has appeared or is threatened. There can be no question that the disease is propagated through the ignorance of the people, and sometimes, let us add, of physicians, as to the nature and physical appearances of the affection. Our own experience in Massachusetts bears this out. Not infrequently during the last few months cases have been discovered relatively late in the course of the disease, after affording ample opportunity for its transmission to others. This danger is enhanced by the mildness of the affection, as recently manifested.

Since this is so, and since for various reasons cases are apt to go unrecognized and thereby become a menace to others, it is the part of policy for those in authority to disseminate knowledge which will tend to minimize this danger. By this means it is probable that a much more ready recognition of the disease would be attained, inasmuch as the people would tend to become interested and to co-operate more fully with the appointed guardians of the public health than is at present the case. We hope that other States will see fit to follow in the footsteps of Indiana, for in the case of small-pox public education means a more successful prophylaxis than is likely to be attained by law and compulsion.

AN ARMY SANITARIUM FOR TUBERCULOSIS.

By direction of the Secretary of War, the Surgeon-General of the Army has recently been authorized to establish a general hospital at Fort Bayard, N. M., as a sanitarium for the treatment of officers and enlisted men of the army suffering from pulmonary tuberculosis, and hereafter transfers of enlisted men suffering from that disease may be made to the new hospital upon the recommendation of medical officers of the army. Orders have been issued to the quartermaster's department to put in a good state of repair such buildings at Fort Bayard as the surgeon-general may designate as necessary for the establishment of the hospital. The surgeon-general is also authorized to provide for the care and treatment of discharged soldiers entitled to the benefits of the United States Soldiers' Home, Washington, D. C, who may be sent to the sanitarium by the Board of Commissioners of the home. The expenses for the maintenance of such discharged soldiers will be paid from the funds of that institution.

The establishment of this sanitarium is the logical outcome of the practice which has prevailed since 1892 of transferring soldiers in the early stages of phthisis to the various military stations in Arizona, New Mexico and Southern California, in order to give them the advantage of a more favorable climate. While no large number has been so transferred, the results have been sufficiently favorable to warrant the action just taken — about twenty per cent. of such transfers having been followed by recovery, while the progress of the disease has been arrested in a large proportion of cases. Heretofore, these phthisical individuals were scattered among the posts of Apache, Huachuca, Grant, Bayard and the barracks at San Diego, and their treatment was merely incidental to the routine hospital work at these stations. This practice presented obvious disadvantages, both to the patient and those with whom he was placed in contact, and it is believed that under the new system considerably more favorable results may be anticipated. It will be remembered that the abandoned military reservation of Fort Stanton, N. M., was a few months since transferred to the Interior Department for use by the Marine-Hospital Service in the treatment of consumption, and it seems rather unfortunate that these two sanitaria, only a short distance apart, could not be combined into one large establishment, instead of being maintained as separate institutions. At present the navy, in which a high proportion of pulmonary tuberculosis necessarily exists, has no place for the reception and scientific treatment of the incipient consumptive, nor has its enlisted force the numerical strength to warrant the establishment of a third institution of this character to meet its particular needs. It would seem, therefore, as if both reason and economy demanded a single large Government sanitarium, modelled on the plan so successful in its workings at the Army and Navy General Hospital

at Hot Springs, Ark., where are admitted the officers, cadets and enlisted men of the military and naval service, the officers of the Revenue-Cutter Service and Marine-Hospital Service and the honorably discharged soldiers and sailors of the regular and volunteer army and navy. This hospital has been ably administered and well patronized, and shows that there need be no disadvantage or official friction where patients are derived from various sources. A favorable climate is recognized as the most powerful factor in inducing recovery in tuberculosis, and provision should be made by which all classes entitled to receive medical attendance from the Government should be equally favored in this respect. The multiplication of establishments for this purpose is needlessly expensive, and if consolidated under one head, preferably a medical officer of the army trained for the position by previous command of one of the immense military hospitals which have been in constant operation since the outbreak of the war with Spain, their capacity for good would be increased and an excellent administration assured.

A SIGN OF PROGRESS.

It will be remembered that a few years ago Dr. Weir Mitchell published a vigorous protest against the lack of productiveness in research work of large institutions, chiefly of those devoted to the care of the insane. He pointed out that in spite of the best possible opportunity, practically nothing had been accomplished up to the time at which he wrote. The suggestions made by Dr. Mitchell were not all graciously received, but they undoubtedly had a certain effect, as unpleasant suggestions are apt to, in arousing men engaged in institution work to a renewed sense of their possibilities. In any case, whatever the reason may have been, it takes no very critical eye to see that a change of far-reaching character has been introduced and is becoming more and more evident each year. This has been demonstrated in several ways. First and most important, by the appointment of trained men to positions in institutions at which patients remain for long periods of time. It is being clearly recognized that the duties of institution physicians are much broader than is implied in the mere physical care of those entrusted to them. If the hospital completely fulfils its function, the patients must be studied by those who have ample time and training for such study, and this should be continued into the post-mortem room and laboratory. As a result of this growing feeling pathologists have been appointed, and with these appointments the whole spirit of institution life has changed. They have developed, in many cases, into prolific fields of research, to the lasting benefit of the patient, as well as to the cause of science. In other words, institutions have become hospitals and not merely asylums, a term which we find everywhere, and rightly, falling into disuse.

With the development of the spirit of research has naturally and inevitably come the growth of the laboratory, as a necessary adjunct to all well-regulated hospitals. Apart from the individual laboratories which now exist in nearly all of our institutions, we have, within the last few years, seen a plan take root and grow in New York City, under the direction of Dr. Ira Van Gieson, which is without doubt destined to prove of incalculable value to the development of investigation in the insane hospitals of New York State and of the whole country. We refer, of course, to the Pathological Institute of the New York State Hospitals. In this we have a central station, to which members of hospital staffs may come to learn methods, and from which they go to carry out work in the several institutions to which they may belong, the associates of the laboratory itself meanwhile devoting themselves particularly to the various problems which psychiatry and allied sciences present.

As a natural consequence of this new enthusiasm, the need has grown for a means of publication of the results of research. This has led, on the part of New York State, to the publication of the *Archives of Neurology and Psychopathology*, an admirably edited and printed quarterly, to which we have previously had occasion to refer in these columns. Individual institutions are following this example, and we may expect to see a constantly growing number of such publications as time goes on. For example, as we write, we have before us a volume of 236 pages, done in the very best style of the bookmaker's art, entitled "The Bulletin of the Ohio Hospital for Epileptics," and edited by Dr. A. P. Ohlmacher, who is also the chief contributor. In it Dr. Ohlmacher presents the results of his researches on the pathology of epilepsy, a paper of much importance, with various collateral matters of more than usual interest. The only regret is that such an admirable publication should not have a wider circulation.

We regard it as a most hopeful sign of the times that opportunities are now everywhere being grasped, that valuable material is being used, instead of being almost universally neglected, as was the case not many years ago. We are gradually learning the lesson that the institution which deals with more or less fixed patients suffering often from chronic disease is the place of all others for the investigation of some of the most subtle and important problems of medicine. Dr. Mitchell's protest could not have been uttered at the present time, true as it may have been when he wrote, for now some of our very best work is coming from the institutions he was holding up to criticism, and more is sure to follow. This fact certainly marks a significant step in advance.

MEDICAL NOTES.

Danger of Epidemics in Porto Rico. — Owing to the appalling loss of life from the storm in Porto Rico, the sanitary condition of the island is thought to

be in a dangerous state and a serious epidemic of disease is feared.

A NEW BUILDING FOR MCGILL UNIVERSITY. — We learn from *Science* that McGill University proposes to erect at the cost of $70,000 a building for its departments of hygiene, pharmacology and medical jurisprudence. In the medical department of this university Dr. T. W. Burgess has been appointed professor of mental diseases.

YELLOW FEVER IN FLORIDA. — It is reported that between twenty-five and thirty cases of yellow fever have occurred at Key West, though not in a virulent form. A careful house-to-house canvass is being made and strict quarantine regulations established. It is probable that the number of cases is increasing, but the situation can no doubt be held in control.

INSANITY IN ENGLAND. — The recently issued annual report of the English Commissioners in Lunacy shows, according to the *Medical Record*, a great increase in insanity in England and Wales. On January 1st of the present year there were 105,086 persons adjudged insane, an increase of 3,114 over the previous year. The increase occurred among those of all social grades, being greatest, however, among paupers. It is thought a Government inquiry will be made into the causes of this increase.

THE NEW PATHOLOGICAL MUSEUM AT BERLIN. — The *Philadelphia Medical Journal* states that the completion of the magnificent new museum of pathological anatomy in connection with the Royal Charité Hospital may be regarded as one more triumph of its illustrious director, Professor Rudolph Virchow, and as significant of the wonderful strides that have been made in this branch of medical science at Berlin in the past as well as of the brilliant promise of the future.

MEDICAL STUDENTS IN THE SWISS UNIVERSITIES. — According to the *British Medical Journal*, the total number of students of medicine in the universities of Switzerland in the summer semester of 1899 is 1,153, of whom 344 are women; of these only 25 are Swiss. The students are distributed among the several universities as follows: Basel has 128, of whom 3 are women; Berne 247, of whom 87 are women; Geneva 277, of whom 90 are women; Lausanne 151, of whom 41 are women, and Zürich 350, of whom 123 are women.

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, September 6, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 45, scarlet fever 14, measles 1, typhoid fever 34.

THE BOSTON FLOATING HOSPITAL. — The trips of the Floating Hospital have been discontinued after a very successful season.

NEW YORK.

THE HEAVIEST PATIENT ON RECORD. — Perhaps the largest patient ever received at Bellevue Hospital was a trombone player, thirty-four years of age and weighing four hundred pounds, who was taken there on September 2d, suffering from hemiplegia. It required eight men to lift him from the ambulance, and in the ward to which he was taken two cots were lashed together and especially braced to sustain the man's weight.

GYMNASTICS IN THE VACATION SCHOOLS. — A pleasing feature of the winding up of the vacation schools was the first annual gymnastic tournament of the pupils of the public playgrounds and open-air gymnasiums maintained by the Board of Education, which was held at Crotona Park, in the Borough of the Bronx, on September 1st. This is an entirely new branch of public-school work, and the exhibition attracted much interest. There were entered thirty-two teams of ten boys each, who did work on the vaulting bar, parallel bars, combination ladder, and tumbling mats. There were also some boxing and wrestling matches.

A FAMILY TREATED FOR RABIES. — A whole family, consisting of father and mother, and three children, who were recently bitten by a pet dog, believed to be suffering from rabies, at their home in Hamesford, Ontario, has been received at the New York Pasteur Institute for treatment.

ARMY NOTES.

EUCALYPTUS AND MALARIA. — Investigations, under orders from General Brooke, have been instituted in Cuba with reference to the eucalyptus globulus as an antimalarial agent. This tree, which is largely planted in the Roman Campagna and by the French in Algeria, is said to have rendered former malarial districts much less unhealthful. The city of Mexico is cited as another instance, where the Vigo Canal, the floating gardens and other malarial districts are now well stocked with young trees, with the result that places which were once marshy and unhealthful have been rendered dry and salubrious. General Wood is reported to have strongly endorsed a requisition for these trees for Santiago.

INCREASE OF HOSPITAL FACILITIES IN THE PHILIPPINES. — The chief surgeon at Manila has been directed to take immediate steps looking to the enlargement of hospital facilities in the Philippines to conform to the increased force of 63,000 men which it is expected will be available for duty in December. As the time required for the erection of large frame hospitals, such as were erected in this country at Hampton, Savannah and San Francisco, is at least six months, it will be necessary to depend upon buildings already constructed, supplemented by tent hospitals. For the latter purpose 500 hospital tents, in addition to those already in Manila, have recently

been forwarded, and the chief surgeon has been instructed to have these hospitals in readiness prior to the arrival of the newly raised volunteer troops from the United States.

AN ARMY MEDICAL EXAMINATION AT MANILA. — Recent orders constitute the medical officers on board the hospital ship *Missouri* into an examining board, for the purpose of passing upon the merits of candidates for commissions in the medical corps now serving in the Philippines. At the last examination, held during the past winter, the medical men serving in the *Orient* were debarred by distance from appearing as candidates. There are now several existing and anticipated vacancies in the corps and these Surgeon-General Sternberg has justly decided should be filled from the score or more applicants who have rendered such valuable service at the front. The examining board is directed to convene as soon as Manila is reached.

MOVEMENTS OF THE ARMY HOSPITAL SHIPS. — The army hospital ships *Relief* and *Missouri*, now at San Francisco and New York respectively, will leave for Manila about the end of August. The *Relief* carries a full load of medical stores and a detachment of twenty female nurses. The *Missouri*, now being refitted for the trip, will sail *via* Suez, carrying a large amount of medical supplies, a number of medical officers and a detachment of the hospital corps, numbering one hundred and fifty men.

ILLEGITIMACY IN THE BRITISH WEST INDIES. — The report of the registrar-general for the island of Jamaica, for the year 1898, deplores the falling of in marriages among the poorer classes, the rate per 1,000 population having undergone a steady annual decrease from 5.5 per 1,000 in 1891 to 3.7 in 1898. This is a discouraging indication of the social conditions on the island but is consistent with the high and increasing rate of illegitimacy, since of the 28,447 births no less than 17,729 — or 62.3 per cent. — occurred out of wedlock. In 1897 the proportion of illegitimacy was 61.1 per cent., this figure being much above the average for the preceding decade. The proportion of deaths of legitimate and illegitimate children under one year old to each 100 births of same was 13.87 for the former and 20.08 for the latter. The report compares the illegitimacy in Jamaica with that of the other British West Indian colonies, using the latest statistics, showing the rate of illegitimate births per 100 births as follows: British Guiana, 72.6; Dominica, 69.5; Antigua, 68.5; Jamaica, 62,3; St. Lucia, 59.38; Trinidad, 58.1; St. Vincent, 56.4; Grenada, 49.63; British Honduras, 36.73; Bermuda, 13.2. In Jamaica the blacks outnumber the whites in the proportion of 44 to 1, and are said to be largely relapsing into the semi-barbarous state prevailing among the blacks of San Domingo and Haiti. The low amount of illegitimacy in Bermuda corresponds with the unusually small proportion of venereal disease noted among the British troops on that station.

A RECENT MEDICAL REQUISITION. — An idea may be obtained of the magnitude of the work of the medical department in the Philippines from a requisition for medical supplies made by the chief surgeon of the troops now serving in those islands. The requisition, recently received and filled, included 40 items, among them being 10,000,000 quinine tablets; 7,500,000 grains of quinine in bulk; 20 tons of epsom salts; 5,000 bottles of paregoric; 3,000 bottles of iodoform; 8,000 bottles of collodion; 5,000 bottles of chloroform; 2,500 tins of ether; 10,000 quarts of whiskey and 7,000 quarts of alcohol. There were also 600,000 compound cathartic pills; 1,000,000 tablets of strychnine; 1,600,000 tablets of salicylate of soda; 12,000 yards of mustard plasters; 3,000 yards of adhesive plaster; 50,000 yards of plain gauze; 5,000 yards of unbleached muslin; 50,000 sterilized bandages; 96,000 roller bandages and 4,000 pounds of absorbent cotton. The order also included 5,000 pieces of each kind of crockery and cutlery necessary to equip hospital mess tables.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUGUST 26, 1899.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 2, 1899.

E. R. STITT, passed assistant surgeon, detached from the Bureau of Medicine and Surgery, September 25th, and ordered to the "Hartford."

W. M. GARTON, assistant surgeon, detached from the "Annapolis," when placed out of commission, and ordered to the Naval Academy. Order of August 28th modified: when detached from the "Annapolis" ordered to the Norfolk Navy Yard for duty on the "Franklin," instead of to the Naval Academy.

I. N. HURD, pharmacist, detached from treatment at the Naval Hospital, Mare Island, Cal., and granted sick leave for three months.

J. C. ROSENBLEUTH, passed assistant surgeon, detached from the "Nashville" and ordered to the Naval Hospital, Chelsea, Mass., for treatment.

M. S. GUEST, passed assistant surgeon, detached from the Boston Navy Yard and ordered to the "Wabash."

H. A. DUNN, assistant surgeon, detached from the Washington Navy Yard, September 2d, and ordered to the Port Royal Naval Station.

A. STUART, assistant surgeon detached from the Port Royal Naval Station, September 2d, and ordered to the "Yankton."

D. B. KERR, assistant surgeon, detached from the "Yankton" and ordered to the "Marietta" upon report of relief.

M. K. JOHNSON, assistant surgeon, detached from the "Marietta" and ordered to the "Nashville."

R. WAGGENER, pharmacist, ordered to the Army and Navy General Hospital, Hot Springs, Ark., for treatment.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING AUGUST 24, 1899.

CARMICHAEL, D. A., surgeon. Granted leave of absence for thirty days. August 23, 1899.

WASDIN, EUGENE, surgeon. To proceed to Marshall, Va., on special temporary duty. August 18, 1899. Detailed as delegate to the International Medical Congress to meet at Brussels, Belgium, September 4, 1899. August 21, 1899.

PETTUS, W. J., surgeon. Granted leave of absence for one day. August 19, 1899.

STIMPSON, W. G., passed assistant surgeon. Granted leave of absence for thirty days from August 19, 1899. August 18, 1899.

OAKLEY, J. H., passed assistant surgeon. To proceed to Paducah, Ky., on special temporary duty. August 21. 1899.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for ten days. August 23, 1899.

FRICKS, L. D., assistant surgeon. Detailed as inspector of unserviceable property at Norfolk, Va. August 21, 1899.

CAMINERO, H. S., acting assistant surgeon. Detailed as quarantine officer for the port of Guantanamo, Cuba. August 22, 1899.

RECENT DEATHS.

WILLIAM H. CAMMER, M.D., of Brooklyn, died on August 30th, after a brief illness. He was seventy-eight years old and was born in Madras, India. His medical studies, which were begun in London, were completed in Germany, and in 1848 he came to the United States. For sixteen years he was examining physician for the Immigration Commissioners at the old Castle Garden Station.

JAMES FERLEY, M.D., of Williamsburg, Borough of Brooklyn, died suddenly on August 30th, of cardiac disease. He was born in London, Eng., and was fifty-five years of age. At the time of his death he was chief of the Surgical Staff of St. Catherine's Hospital.

JOHN J. LINSON, M.D., died of cardiac disease at his home in Tarrytown, N. Y., on August 27th. He was born in New York City in 1837 and was a graduate of the College of Physicians and Surgeons. During the Civil War he served as surgeon of the 6th New York Heavy Artillery. He is credited with having invented the plan of marking men with nitrate of silver to prevent bounty jumping. For three years he was president of the Westchester County Medical Society.

BOOKS AND PAMPHLETS RECEIVED.

Tetany, with Illustrative Case. By George W. Miles, A.M., M.D., Oneida, N. Y. Reprint. 1898.

Chemicolegal Testimony: Strychnin. By G. H. Meeker, M.S., Ph.D., Philadelphia Reprint. 1899.

A Review of Recent Legal Decisions affecting Physicians, Dentists, Druggists and the Public Health, together with a Brief for the Prosecution of Unlicensed Practitioners of Medicine, Dentistry or Pharmacy, with a paper upon Manslaughter, Christian Science and the Law, and Other Matter. By W. A. Purrington, of the New York Bar, Counsel of the Dental Society of State of New York, etc. New York: E. B. Treat & Co. 1899.

Practical Diagnosis: The Use of Symptoms in the Diagnosis of Disease. Fourth edition, revised and enlarged. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; Member of the Association of American Physicians, etc. Illustrated with 205 engravings and 14 colored plates. Philadelphia and New York: Lea Brothers & Co. 1899.

On the Relation of the Nervous System to Disease and Disorder in the Viscera. Being the Morison Lectures delivered before the Royal College of Physicians in Edinburgh in 1897 and 1898. By Alexander Morison, M.D. (Edin.), Fellow of the College; Member of the Royal College of Physicians in London; Physician in Charge of Out-patients to the Great Northern Central Hospital and the Children's Hospital, Paddington Green, etc. Edinburgh and London: Young J. Pentland. 1899.

A Text-book of Mental Diseases, with Special Reference to the Pathological Aspects of Insanity. By W. Bevan Lewis, L.R.C.P. (Lond.), M.R.C.S. (Eng.), Medical Director, West Riding Asylum, Wakefield; Lecturer on Mental Diseases at the Yorkshire College; Examiner in Mental Diseases to Victoria University. Second edition, thoroughly revised, enlarged and in part rewritten, with illustrations in the text, charts and 26 lithographed plates. Philadelphia: P. Blakiston, Son & Co. 1899.

The Medical Complications, Accidents and Sequelæ of Typhoid or Enteric Fever. By Hobart Amory Hare, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc. With a special chapter on the Mental Disturbances following Typhoid Fever. By F. X. Dercum, M.D., Clinical Professor of Diseases of the Nervous System in the Jefferson Medical College. Philadelphia and New York: Lea Brothers & Co. 1899.

Progressive Medicine: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc. Volume I. March, 1899. Surgery of the Head, Neck and Chest; Diseases of Children; Pathology; Infectious Diseases, including Croupous Pneumonia; Laryngology and Rhinology; Otology. Philadelphia and New York: Lea Brothers & Co. 1899.

Pulmonary Tuberculosis: Its Modern Prophylaxis and the Treatment in Special Institutions and at Home. Alvarenga Prize Essay of the College of Physicians of Philadelphia for the year 1898. Revised and enlarged by S. A. Knopf, M.D., Paris and Bellevue Hospital, N. Y., Physician to the Lung Department of the New York Throat and Nose Hospital; formerly Assistant Physician to Professor Dettweiler, Falkenstein Sanatorium, Germany, etc. With descriptions and illustrations of the most important sanatoria of Europe, the United States and Canada. Philadelphia: P. Blakiston, Son & Co. 1899.

Original Articles.

INTUSSUSCEPTION.[1]

BY JOHN C. MUNRO, M.D., BOSTON.

That intussusception is not rare is shown by the fact that over 500 cases have been reported within the last twenty-five years. According to Leichtenstein, 40 per cent. of all cases of intestinal obstruction are due to this lesion. Probably three-fourths of the cases occur in infants, though no age is exempt, even the fetus at full term not escaping. The lesion is due to the swallowing by one portion of the gut of its neighboring piece which has become constricted in consequence of a vigorous contraction of its circular fibres. According to Power, children are predisposed apparently on account of the greater length of the mesentery.

All cases should be considered, in the interest of the patient, to be surgical from the beginning. A strangulated hernia has long since ceased to be a medical disease; how much more should an internal strangulation with its similar possibilities be within reach of surgical interference if necessary. As in appendicitis, every case may not demand operation, but the responsibility should be placed in the hands of one who is ready and able to operate at the earliest opportunity.

Intussusception may be caused by sudden blows or injuries, muscular efforts, tumors of various kinds, typhoid or tubercular ulcerations, diarrhea and possibly vomiting and coughing.

The invagination is found in more than half of the cases in the ileocecal region, though other portions of the intestinal tract may be involved, Chiari and Engel each having seen a partial invagination in the stomach. The jejunum is comparatively rarely affected.

The symptoms in a typical case are sudden and acute abdominal pain, usually coming on at night, vomiting and stools containing mucus and blood. There may be diarrhea or obstipation. A tumor, not necessarily sausage-shaped, can be felt in the abdomen, generally on the right side, but until peritonitis has begun, spasm is absent or slight in degree. As the intestine becomes more and more constricted, congestion, stasis, infiltration and necrosis follow. Owing to the greater elasticity of the constricting ring as compared with the ring in external hernia, we are less liable, comparatively speaking, to find strangulation. Furthermore, the inner tubes being more liable to become gangrenous than the sheath, peritonitis may be escaped by the passage of the gangrenous portion along the digestive tract. But, in actual practice, it is not safe to rely on so slight an advantage, or to consider the condition less serious than it is, to wit, one of the most serious than can confront the surgeon.

Intussusception may be acute, chronic, chronic with acute exacerbations, single or multiple, direct or reversed.

Peritonitic adhesions may not form for weeks, or may begin with the onset of the invagination.

Spontaneous recovery may take place by disinvagination or by separation of the inner tube and evacuation later; in the latter way several feet of gut may be lost, one observer (Peacock) having seen eight pieces, aggregating twelve feet, passed during the course of three years. Disinvagination without any interference beyond medical treatment occasionally takes place, but such a fortunate outcome is rarely to be anticipated. Of spontaneous separation Rydygier says that it is very satisfactory but rare, "and to speculate on a chance accident is not an established therapeutic procedure." Many such cases die later of perforation, peritonitis, stricture, etc. According to Senn, young children and infants seldom, if ever, recover in this way.

Treatment by mechanical distention with liquids, air or gas may be successful if employed early, that is, within the first twenty-four or forty-eight hours at the utmost. In acute cases it is best given with full anesthesia and the patient inverted, all preparations for laparotomy in case of failure, necessity or doubt having been made. The pressure should be slight, not over two pounds if gas be used, or if a liquid, the reservoir should not be over two or three feet above the patient. A low intussusception may rarely be pushed back by a finger or tube passed into the rectum.

There is considerable shock from such a simple procedure, and many cases of rupture of the intestine during injection have been recorded. It is difficult to reduce the final inch of the invagination, and without actual inspection one cannot tell whether the reduction has been complete or not, so that the cases of recurring intussusception are probably due to the failure of complete disinvagination and not to a fresh, independent attack. Barker says that there is a tendency of the bowel to unroll itself *up to* the point at which it first began, but no farther; in other words, the supposed reduction is not a complete one, and abdominal palpation under such conditions may fail to show any tumor.

In brief, injection is justifiable in chronic cases; where the patient refuses operation in acute cases; when beyond surgical aid and within a few hours after the onset of the attack. If the first attempt in acute cases is not successful it is useless to make a second trial.

All authorities urge operation in one form or another, as early as possible in acute cases and at once after trying a simpler procedure, such as injection, for the same reason that one should be prepared to attack a hernia after failure to reduce it by taxis. In chronic cases it is unwise to delay over a week, simple attempts at reduction having been made meanwhile. The patient should be watched closely to forestall any acute attack. As in operating on the appendix in the interval, the risk of a laparotomy is reduced to its minimum.

After opening the abdomen there are various methods of dealing with the many conditions found. Of these we may consider artificial anus, enteroanastomosis, disinvagination or reduction, complete and partial resection.

Artificial anus has very little to recommend it. There is scarcely a recorded recovery in an acute case. Occasionally a chronic case has survived, and an acute case where a resection has followed the artificial anus which was resorted to to tide the patient along temporarily. As it does not relieve the strangulation or its consequences except the distention and

[1] Read before the Massachusetts Medical Society, June 13, 1899, and recommended for publication by the Society.

obstruction, it must be looked upon merely as a makeshift or an evidence of faintheartedness.

Entero-anastomosis has very little more to recommend it. The intestinal current is, to be sure, reestablished, but the invagination with all its possible and probable consequences still remains. A few cases, less than a dozen, of recovery in adults have been reported, most, if not all of them, being in chronic intussusception.

Disinvagination or reduction is the ideal operation, and if the case is seen early, before necrosis and firm adhesions have taken place, the outlook for its successful employment is good. Everything depends on the interference being early. Fifteen years ago Treves found that the mortality was only 30 per cent. in cases easily reduced, as against 91 per cent. in those reduced with difficulty, and since then, with the improvement in technique and diagnosis, the early operation shows a much lower death-rate.

Where the reduction is not easy on account of firm adhesions there is always a risk of tearing the bowel or of gangrene from the prolonged pressure, and in such suspicious cases it is safer to isolate or drain the area involved. Chronic cases are not necessarily difficult to reduce, even after weeks or months of invagination. In reducing, Senn advises that the edema be treated first as in a phimosis and then that countertraction be made below the apex in order to prevent folding, in the sheath and middle cylinders; occasionally insufflation will add materially in the manipulation. To prevent re-invagination if it appears liable to take place, he also suggest that the mesentery be shortened.

Where, owing to adhesions, tumors, necrosis or perforation, disinvagination is not possible, a resection in one form or another must be resorted to. Probably the simplest method is that devised by Maunsell or some modification similar to that described by Rydygier. The entering gut is sutured to the sheath at the neck without disturbing its position, and then through a longitudinal incision in the sheath the invagination is delivered and amputated near the neck, the free edges of the stump being sutured together, controlling in that way the mesenteric vessels. After dropping the stump back into place, the opening in the sheath is closed. If the invagination cannot be delivered through the side opening after amputation it may be left to come away later in the stools. Where possible a typical Maunsell operation may be done. In this way the least possible amount of intestine is sacrificed and the mesentery is quickly and easily controlled. The use of buttons or spools is unnecessary.

Where the sheath is gangrenous a complete excision is enforced, end-to-end or lateral anastomosis being employed. Here plates or buttons may be used if thought best. Occasionally it may be found that all of the intussusceptum and a portion only of the sheath may be removed. If the intussusception is low down resection may at times be done through the rectum without opening the abdomen.

As, for the most part, all data and methods are based on intussusception in the child and in the ileocecal portion of the intestine, it may be well, in view of the two personal cases reported to-day, to consider, in more detail, invagination in adults and especially when it takes place in the jejunum.

Adding to Braun's table made in 1885 and to Rydygier's table made in 1895 14 cases of reduction or resection in adults over sixteen years of age reported since, we have a group of 72 cases altogether. Undoubtedly there have been many more cases that have been operated upon, but so far as could be discovered no more have been recorded.

Of 21 recoveries after reduction — including the cases of Perceval (1888), Stretton (1894) and Barker (1897) — 13 were in the ileocecal or colic region, four were iliac, one jejunal and three unknown. Thirteen were chronic cases, seven acute, and one unknown.

Of 13 fatal reductions — including the cases of Davies-Colley, White (1889), Richardson (1892) — nine were ileocolic, one each, iliac and jejunal, and two unknown. Seven were acute and six were chronic, probably some of the latter being operated upon during an acute exacerbation. Shock and peritonitis were the main causes of fatal issue.

Of 17 recoveries after resection — including the cases of Hartley (1892), Wassiljew and Munro (1898) — 14 were ileocolic and one each was iliac, colic and jejunal. Six were acute or chronic with acute exacerbations, and nine were chronic, while two were unknown. In two cases (Mikulicz and Wassiljew) the resection was secondary to an artificial anus.

Of 21 fatal resections — including the cases of Abbe (1891), Senn, Robson and Munro (1897) — nine were ileocolic, seven iliac, one colic, two jejunal and two unknown. Fourteen were acute or chronic with acute exacerbations, five were chronic and two unknown. One (Esmarch) was secondary to artificial anus. Nearly all died of peritonitis or shock.

The jejunum was involved in only five of these cases:

(1) White's case, an acute invagination ten inches long and two and one-half feet from the pylorus, died on the table, the operation being abandoned.

(2) Stutsgaard's case, caused by a lipoma and of unknown duration, died in five days of peritonitis after resection of 128 centimetres.

(3) Robson's case, of seven days' duration, died after resection of four feet and an end-to-end anastomosis.

(4) Borch's case of acute ileojejunal invagination recovered after disinvagination.

(5) Writer's case of recovery after resection of thirty-two inches of jejunum.

The earlier cases, like those reported by Velse, Fuchsius and others at the beginning of the present century were naturally cases of reduction, many of them being easily replaced. When in recent years resection began to be employed it was at first almost uniformly fatal, but with the improvement in technique the mortality has fallen nearly one-half, and in all probability it will never be much less because, with earlier diagnosis and operation, resection will be replaced by reduction, leaving only the desperate and neglected cases for the more serious operation.

Where the lesion involves the upper portion of the intestine any procedure must of necessity be fraught with more danger than in the cases in which the lower part of the tract is involved, but fortunately the latter region is far more frequently affected, so that with early surgical supervision and early interference in both acute and chronic cases after a judicious trial of simpler, non-operative means, many more patients should be saved. It remains in the

hands of the general practitioner to realize the grave possibilities in all cases and to protect himself and his patients by early resort to the surgeon, who, on his part, must appreciate that death, just as in strangulated hernia or in acute appendicitis, is too often the price of a useless delay.

As a contribution to the statistics of operation for intussusception in adults, the writer will add two cases of his own. Both have been briefly reported in the Boston City Hospital Medical and Surgical Reports, Series X, but it may be allowed to give the history of one a little more in detail, the fatal one being dismissed in a few words.

Case I. Male, thirty-seven years old, was admitted to Dr. H. W. Cushing's service at the Boston City Hospital with a history of abdominal pain, obstipation, distention and tenderness in the region of the appendix for sixty hours. Operation under ether. Intussusception of the lower end of the ileum eight inches long and with beginning gangrene was found. Amputation proximally seven inches from the invagination and distally close to the cecum, or about one inch from the invagination, with end-to-end anastomosis, was made. Patient in poor condition at time of operation. On the following day he was still very ill and got out of bed against orders. Sixty hours after operation he died, a partial autopsy showing the abdomen to be full of feces from a rupture in the intestine on the proximal side of the joint, which was tight.

The history of the case of recovery after resection is as follows:

Case II. Chin Yuen, a Chinese laundryman, twenty-one years old, entered Dr. F. H. Williams's service at the Boston City Hospital, October 21, 1898, with a history of intermittent abdominal pain in right upper quadrant for three weeks. There was also an indefinite history of abdominal pain nine months previously, but as the patient talked very little English no definite connection between the two attacks could be obtained. Considerable nausea and vomiting. Bowels regular. Sleep poor on account of pain. During paroxysms he rolled about the bed moaning, and lay preferably on his belly. Pulse 90, regular and of good strength. Heart and lungs negative. A moderately lax, tympanitic abdomen, tender on deep pressure, more resistant on the right side, with increased localized resistance in the right hypochondrium. Two days later there was a leucocytosis of 13,500.

October 27th. No vomiting for five days; the face has lost the drawn expression and he no longer cries with pain. Better appetite and sleep.

October 31st (four days later). No abdominal pain since the 27th, bowels regular, general condition much improved and for several days he has been up and dressed ready for discharge, but two days afterward, on November 2d, he again had an attack of abdominal spasm and passed some blood at stool. Transferred to Dr. George W. Gay's service under the care of the writer. Examination without ether showed a tumor filling the pelvis and pushing the anterior wall of the rectum backwards, the tumor extending upwards along the right iliac fossa to the right hypochondrium. Spasm of the abdominal muscles. In view of his previous history it seemed best to delay in the hope that he would again quiet down enough to allow operation in the interval, but as the symptoms did not improve operation was performed on November 5th.

Operation under ether. — Incision three to four inches long at the outer edge of the rectus, exposing a sausage-shaped tumor extending from beneath the left lobe of the liver to deep in the pelvis, twelve to fourteen inches in length. Towards the lower end were three gangrenous areas that ruptured on handling, allowing pus and feces to escape. After clamping the bowel above and below the intussusception, the mesentery was cut parallel to the gut and the vessels controlled with a continuous half-hitch catgut suture, but owing to the abundant vascular supply additional ligatures were required. In order to gain a little room and to save as much of the bowel as possible the gut was disinvaginated for an inch or more at the neck, but after delivery the circulation was so poor that an additional inch was amputated. After suturing each stump-end with a continuous catgut suture to control the bleeding, an end-to-end anastomosis was made with two rows of a continuous, right-angle silk suture. Owing to the edema and swelling of the gut at the lower end, a good approximation was difficult, but so far as could be seen the joint was a tight one. The mesentery of the upper portion was bluish, and in one place had a small inflammatory patch, but there was apparently life enough to warrant its being retained. To have amputated more gut in order to exclude this bit of mesentery would have necessitated another parietal incision, which in the patient's condition was not justifiable at the time.

A half-pint of salt solution had been injected into the bowel before making the anastomosis; afterwards the abdominal cavity was washed out with hot salt solution, the lower three-quarters of the incision closed with silkworm gut, iodoform wicks and a glass drain being carried in at the upper angle and isolating the region of the joint from the general cavity.

The patient stood the operation, which lasted an hour, fairly well; the pulse at the close being 130 to 140, regular and of fair strength. Strychnia, salt solution and brandy had been given under the skin. Repeated one-quarter grain doses of calomel, and stimulation were ordered.

Good recovery from the operation followed, the bowels moving within twenty-four hours by enema, and broths being retained without vomiting.

November 7th. All wicks loosened and some removed under chloroform, the remainder being taken out two days later and replaced by a light packing.

November 11th. Intestinal contents, bile and pancreatic fluid escaped from the sinus to-day, but the general condition of the patient remains good. He was then put on rectal feeding, but as symptoms of starvation appeared a second operation was advised.

November 15th. *Operation under ether.* — At the bottom of the sinus a small opening into the bowel lay an inch and a half to the inside of the line of the parietal wound, so a second incision was made close to the median line. The opening into the gut, one-half inch in diameter, lay in the midst of gangrenous and granulation tissue. Considerable time was wasted in trying to close this hole, and then the incision was enlarged and the fresh adhesions broken down in order to allow access to the bowel. Owing to its adhesions and short mesentery it split open, not at the original anastomosis, but apparently in line with the

mesentery that was considered doubtful at the first operation. The patient's condition would not warrant prolonged operation, so the ends were sutured together with ordinary silk in mattress sutures passed deeply and at some distance from the edges. Apparently a tight joint was secured. Iodoform gauze drainage. There was considerable shock, but the patient recovered quickly and showed no evidence of peritoneal disturbance. The wicks were removed and he was gaining steadily, when, on the sixth day (November 21st), leakage from both wounds appeared. As the general condition continued satisfactory, a third operation was not undertaken until November 26th, when, under ether, a fine opening admitting a probe, at the bottom of the median incision, was found lying in firm, healthy tissue. This could be easily and completely closed with fine silk. The entire median wound was then thoroughly curetted, filled with strong permanganate solution and closed with silkworm-gut sutures, a small rubber-tissue drain being carried obliquely through the first lateral incision. No shock followed this operation.

Two days later, food, with pancreatic fluid and bile, appeared as of old, but the patient was in good condition, eating solid food and gaining steadily.

December 1st. Considerable digestion of the skin, controlled, at Dr. H. W. Cushing's suggestion, by dressing with tincture benzoin compound.

December 9th. General condition improving rapidly; lateral wound closed; apparently no pancreatic fluid, but a little pus from the sinus.

December 17th. Again a slight escape of pancreatic fluid and bile.

January 18th. The discharge continues about the same, the skin being completely protected by the benzoin.

January 25th. Three heavy silk loops (those used at the second anastomosis) discharged to-day. Patient in excellent condition.

February 4th. Lateral sinus, which reopened temporarily, has again closed.

February 18th. Patient cheerful and helpful about the ward.

March 17th. Discharge is now barely sufficient to moisten litmus paper, upon which it uniformly gives an acid reaction.

March 27th. Sinus healed. Patient fat and healthy.

April 11th. Wounds firmly closed; patient discharged wearing an abdominal swathe.

At the time of operation the intussusception, which was seen to be in the jejunum, was apparently a reversed one, but careful examination later showed that it was a direct invagination. The specimen, when measured after preservation in alcohol, showed that at least thirty-two inches had been excised.

It would have been better to have operated at the time the patient was ready to be discharged, or, at the latest, when the recurrence of the acute symptoms began, as in that way a partial excision might have been substituted for the complete one. No cause in the shape of a tumor or ulcerations could be found.

ANTHRAX EPIDEMIC. — A slight epidemic of anthrax, according to the *Journal of the American Medical Association*, has appeared among cattle in southern Chester County, Pa. The disease has also appeared in the region of Chambersburg, four cattle and two horses having died within the past few days.

THE GROWTH AND EXTENSION OF CARCINOMA.[1]

BY WILLIAM T. COUNCILMAN, M.D., BOSTON.

THE carcinoma is a tumor which arises from epithelial tissues and is characterized by unlimited growth locally and by the formation of tumors of a similar structure in other parts of the body. When we examine its microscopic structure we find that it is composed of two sorts of tissue: (1) epithelial cells arranged for the most part in solid masses, which vary in their size and form, growing in spaces which are called alveoli; (2) connective tissue which surrounds the alveoli and bears the blood-vessels for the nutrition of the cells in the alveoli. This connective tissue is called the stroma. Neither stroma nor blood-vessels penetrate the masses of epithelium. When we examine normal epithelial structures we find a very similar arrangement of tissues — epithelial cells growing in the closest juxtaposition with connective tissue, but never penetrated by it. Whether we consider covering epithelium or glandular epithelium, the arrangement of tissue is always the same.

If we take any normal epithelial structure and suppose that the cells at some point begin to multiply with unlimited activity and penetrate into the adjoining connective tissues, we have the structure of the carcinoma. It is not sufficient for the epithelium to proliferate. Epithelial tissues are the most active of any tissues of the body. Both the covering and the glandular epithelial cells are constantly becoming used up in the course of their physiological activity, and the loss is constantly repaired by the formation of new epithelial cells. This power of regeneration is sufficient not only for the ordinary wear and tear of the tissues, but extensive losses of cells are as easily repaired. Further, the epithelium may be excited to greater activity by various means, and large masses of tissue composed principally of epithelium may be produced. I say principally of epithelium, for, in consequence of a definite law of nutrition, when a tissue is growing actively and requires more food, the old blood-vessels will enlarge and new ones be formed. In consequence of this, along with the epithelial masses, considerable connective tissue with blood-vessels will be produced. An epithelial growth of this kind repeats the formation of the normal structures and is called typical. There is no penetration of the connective tissue by the growing masses of epithelium. There is no normal prototype for the structure of the carcinoma. We express this by saying that the simple hyperplasia we have been speaking of is typical, while the carcinoma is atypical.

When we compare the epithelium in the different epithelial structures of the body, we find differences in the size and form of the epithelial cells, and in their arrangement. These differences are to a certain extent apparent in the carcinomas which arise in different parts, and from the histological examination of the tumor we can say with considerable accuracy from what tissue it has arisen. To explain the growth of the carcinoma it will be necessary to consider for a moment the structure of the connective tissue. This is essentially formed of fibres, between which are cells. It carries the blood-vessels everywhere, and in it the lymphatics arise. In the tissue the cells lie in spaces,

[1] These remarks were illustrated by the projection of photo-micrographs. — Read before the Massachusetts Medical Society, June 13, 1899, and recommended for publication by the Society.

which communicate with adjoining spaces, and from the enlargement and coalescence of these spaces the lymphatics are formed. If we suppose that a carcinoma begins its formation by the epithelium growing outward into this tissue, then the growing cells of the tumor at once find their way into this system of communicating spaces and continue to grow in them. Every mass of epithelial cells is within such a lymph space of the tissue.

When we examine sections from the centre and periphery of a carcinoma we see certain differences in structures. In the periphery the cells stain more sharply and more of them show the peculiar changes in the nuclei by which we recognize cell division than do the cells in the centre. The same thing is seen more clearly when we make a section directly through a small carcinoma. The most active growth is in the periphery. In the centre the alveoli are small, the cells have degenerated, and in some cases have disappeared altogether. All the blood-vessels of a tumor enter from the periphery, and here the best nutrition is offered the cells. The atrophy which goes on in the centre is partly to be accounted for by the compression and occlusion of the vessels by the growing epithelial masses between which they must pass, and partly by the peripheral masses making more active demands for the nutriment which the vessels contain. The size of the single alveolus also has limits. The epithelial masses receive their nutrition also from the periphery because blood-vessels do not penetrate within them. In consequence, the cells on the outside proliferate and the newly-formed cells are pushed into the interior, and with the enlargement of the mass are further and further removed from the source of nutrition. As the alveolus enlarges, degeneration takes place in the central cells. Each alveolus then becomes in its growth a type of the whole tumor. The malnutrition of the centre of the tumor affects not only the epithelial alveoli but the connective-tissue stroma. It loses its characteristic structure, the fibres blend together into a dense mass, and the cells atrophy. It contracts just as cicatricial tissue does, and hence arises the central depression so characteristic of carcinoma in certain places.

Certain names are given the tumor to express the differences of relation between stroma and alveoli. The hard dense tumor due to central degeneration, having small alveoli and dense stroma, is called scirrhus. The softer tumor, with larger alveoli and softer stroma, is called medullary. Both scirrhus and medullary are seen in the same tumor. The hardness of a tumor is frequently only an evidence of the activity of the peripheral growth.

Every structure gives way before the growing epithelial masses. This is partly due to pressure and partly to the fact that the epithelial cells demand the nutrition which is provided for the opposing structures. Even the non-maligant tumor presents higher claims for nutrition than the normal tissues. It is not uncommon to find a fatty tumor in an individual so emaciated that almost all the normal fat has disappeared, but the fat cells of the tumor not only suffer no diminution in size and number, but continue to increase. The carcinoma not only grows peripherally as a solid mass, but in various places small masses of cells push out independently into the tissue and form new centres of growth which gradually coalesce with the central mass. The contraction of the tumor due to central degeneration is particularly seen in carcinomas of the alimentary canal. In this the central part of the tumor is connected with the lumen. The degenerated necrotic portions are invaded by bacteria, which find there a suitable soil for growth, and inflammation and ulceration results. In the stomach the necrotic portions are digested by the gastric juice. The stricture of the intestine results both from the masses of the tumor pushing into the lumen and from the contraction which constantly accompanies the degeneration.

The carcinoma not only tends to grow locally in the way we have seen, but similar tumors are formed elsewhere. In carcinomas these secondary or metastatic tumors are found in those lymphatic glands which are connected with the primary tumor by lymphatic vessels. In carcinomas of the alimentary canal the secondary growths are found not only in the lymphatic glands but in the liver, the connection being by blood-vessels of the portal system. The metastases repeat the structure of the primary tumor. Differences in the size and arrangement of the cells which characterize the primary tumor are found in the secondary. The same tendency to degeneration and the same form is seen in the secondary. Something capable of producing the same growth must be carried from the primary tumor to form metastases. We can trace the growth of the metastases much better than we can the growth of the primary tumor. By examining those lymphatic glands of the axilla removed with a carcinoma of the breast, which to the naked eye present no enlargement or deviation from the normal, the beginning of the metastasis can be seen. It begins in the periphery of the gland where the lymphatics coming from the primary growth enter. Cells of the same character as those in the primary growth are found in the lymph sinuses, and they grow here, the remainder of the gland forming the stroma.

The growth advances along the lymphatics in two ways. Solid masses of cells probably connected with the primary growth may push their way along the lymphatic vessels. I have seen all the lymphatic vessels of the scrotum injected with carcinoma this way, separate nodules being formed at intervals by more active proliferation of the cells in the lymphatics. In the carcinoma of the stomach it is not at all uncommon to find the lymphatics of the peritoneum over the tumor filled in this way with masses of cells. Secondly, not only can we trace these masses of cells in the lymphatic vessels, but by examining the tissue which is in the neighborhood of a carcinoma and which is apparently not affected, we can often find single epithelial cells within the lymphatics. In certain cases the tumor cells may push their way into blood-vessels. In carcinoma of the alimentary canal metastases both by the lymphatics and blood-vessels is the rule. This is probably to be explained by the presence of such numerous and thin-walled veins in the tissue.

We may certainly regard the metastases as due to the conveyance, by either the blood-vessels or lymphatics, of cells from the primary tumor to a distance. The proof of this is the close connection of the cells of the tumor with the lymphatic system, the presence of cells showing similar structure, mode of growth and tendency to degeneration in the secondary tumors, the beginning of secondary tumors in the lymphatic glands where the lymphatics enter the gland, and the presence not only of cell masses but of individual cells in the lymphatic vessels. The full recognition by surgeons

of the intimate relation between the cells of the tumor and the lymphatics has led to those methods of operation which have so reduced the danger of recurrence. We know that no carcinoma can be found so recent in its development that the lymphatic glands belonging to the part may not be affected. Hence these are removed with the primary tumor. Further, that the way of extension is by the passage of cells from the primary tumor or along the lymph vessels. It is of no use to remove the primary and secondary growth and leave a long street between the two which almost certainly contains straggling cells capable, each of them, of producing a new growth. Hence tissue containing lymphatic vessels connecting primary growth with lymphatic glands is removed as far as possible. Cells from the tumor, each capable of developing a new tumor, may be implanted in the tissues by the knife in the course of operation; hence the care exercised in avoiding incision into the tumor in the course of operation.

When we come to the question of the essential cause of carcinoma we enter the domain of theory. Of these theories we have, first, the influence of trauma, which is supposed to irritate tissues and to cause them to proliferate. Trauma alone has little to be said for it. The infrequency of carcinoma in those parts which are most exposed to trauma and its frequency in those parts least exposed speaks against this. No parts of the body are so exposed to trauma as the hands and feet, no parts less exposed than the mammary gland and the uterus. Even in the pessary days of gynecology carcinoma of the uterus was not made more frequent. Carcinoma of the lower lip, due to smoking, is a favorite example for the traumatist. Why the infrequency of carcinoma in the upper lip, which must be just as much exposed? It would take an accomplished juggler to hold a cigar in the lower lip. The appearance of the tumor at the period of life when traumas of all sorts are less apt to take place speaks also against it.

(2) The theory of Thiersch that the essential element in the production of a carcinoma is a degeneration of the connective tissues, in consequence of which the epithelium more easily grows into it. Such degeneration, if true, should be capable of demonstration, but has not been demonstrated.

(3) The theory of embryonic residues of tissue included in the normal tissues and capable of the enormous capacity of growth which characterizes embryonic tissue. This theory, though not original with Cohnheim, was taken up by him and advocated with all the force and charm which characterizes his work. In favor of this it must be said that there is much analogy between tumors and embryonic tissue, and that such remains of embryonic tissue may exist in the body and that tumors may develop from them. Considered purely as a theory, there is undoubtedly more to be said in favor of it than of any of the others. A modification of this theory has been advocated by Ribbert, who supposes that not only such embryonic tissues develop into tumors, but that when masses of epithelium become separated from their organic connection with other cells they may develop into carcinoma. There is danger in even discussing these theories that one may be tempted to advance one.

Probably the theory which of late is having the most attention paid it is that of the parasitic origin of carcinoma. From a purely theoretical point of view, there is much which speaks for and more against it. It must be considered a theory, for as yet parasites have never been demonstrated in a carcinoma, or certainly not in such a connection with it that they should be considered as causal. From a theoretical point of view, there are certain things which at first sight seem to favor the parasitic theory. First, the apparent increase in the number of deaths caused by the malignant tumors. If these tumors are due to embryonic causes or trauma, or such constantly operable causes, there would be no likelihood of increase. If due to parasites they could, like the other infectious diseases, show periods of increase and decline. There can be no doubt, from the numerous articles which have appeared on this subject, that the general mortality statistics show on the face a marked increase in cancer mortality in the last twenty-five years. It is possible to take mortality statistics and prove many things by them. Only those who know how mortality statistics are gathered, who see the crude returns before they are interpreted by the clerks in health offices and arranged in fair columns of figures, know their full unreliability. The exponents of protection and free trade have shown what can be done with the fairly accurate economic statistics. The more accurate statistics of insurance companies do not show this increase. The apparent increase deduced from the general statistics can be referred to a number of causes. There has been an increase in longevity, due principally to diminished mortality in the infectious diseases. Carcinoma is essentially a disease of later life, and more people reach what may be termed the carcinoma age. The diagnosis of carcinoma, especially of the internal organs, has become more accurate, and deaths are now properly attributed to this disease which were formerly put down under other heads. Deaths from carcinoma were formerly concealed as much as possible, so great was the horror of the disease and the fear of heredity. Hospital surgeons gain a general idea of increase from the number of cases who come to the hospital for operation, due to the great success which now attends such operations. The disease carcinoma in some respects shows a similarity to the chronic infectious diseases. Like these, it commences in some locality, and from this it extends to other parts by means of the blood or by lymphatic vessels. In carcinoma, as in infectious diseases, there develops after a variable time, a condition of wasting and malnutrition, which is termed cachexia. When we examine more closely, the analogy is not so evident. In the first place, the tissue lesions are totally different. There is a great deal of similarity in the lesions of all the infectious diseases. They consist in a combination of degeneration and proliferation of tissue. In certain of them, as in tuberculosis, the character of the degeneration produces a typical lesion from which it is possible to make a diagnosis, though not with absolute certainty. All the new tissue formed is of an indifferent type and of the general character of the granulation tissue of inflammation. In the metastases the same general character of lesion is produced as in the primary. Opposed to this, in carcinoma a definite tissue is produced consisting of epithelium growing into a connective-tissue stroma. It is not an indifferent tissue which might arise from proliferation of the connective tissue, but is a definite tissue formation consisting of epithelial tissue in a definite relation to connective tissue. Moreover, the metastases show the

same type. It is possible to have in the liver secondary to an adenocarcinoma of the rectum an almost perfect reproduction of the glands of Lieberkühn. If the cells are small in the primary growth, if they have any peculiarity in arrangement, if they show any peculiar form of degeneration, the same is true of the metastases. The metastasis which has been used by the exponents of the parasitic theory as showing the analogy between carcinoma and infectious diseases cannot be produced by parasites alone. In the infectious diseases the primary lesion is usually at some point which is open to infection from without, as the lungs in tuberculosis. In carcinoma the disease is most frequent in those parts in which the ordinary infections are most rare. Certain peculiar bodies are found included in the cells of carcinoma which have been considered as parasites. It is perfectly true that we do find in the epithelial cells of carcinoma small structures of whose nature we are for the most part ignorant. We do not better the situation by saying, therefore, they must be parasites. They show no definite size or form, they have no definite reaction to the aniline dyes, and if parasites, they differ from any known type. It is not impossible that carcinoma may be due to the invasion of the tissue by a parasite. If true, the invasion must take place only in the latter half of life, in places least exposed to invasion of the ordinary infectious agents, the parasite must enter every cell, causing it to proliferate and grow in a peculiar way, and must be carried with the cell into other parts of the body and there again cause the same peculiar cell growth.

The enormous advance in our knowledge of disease in the last twenty-five years has scarcely affected the malignant tumors. The classification has been improved and we know their structure rather better, and that is about all. There is need now not of any new theory, but of close investigation. The parasite theory must be taken up and definitely proven or set aside. The question of their inoculability must be determined. The investigation should cover not only the malignant tumors in man, but possibly a more fruitful field may be found in the tumors of lower animals, particularly the common tumors of fish. Such investigations are being carried out in various places in other countries and in this, and we confidently believe that the results of these investigations will lead to an increase of our knowledge and, with this, increase in our power to relieve.

TWO CASES OF INJURY OF THE CORD RESULTING FROM FRACTURE OF THE SPINE.[1]

BY JOHN JENKS THOMAS, A.M., M.D., BOSTON.,
Assistant in Nervous Diseases, Boston City Hospital; Assistant Neurologist, Children's Hospital, etc.

(Concluded from No. 10, p. 235.)

Microscopical examination. — Sections were made at various levels and stained with hematoxylin and eosin; hematoxylin and picric acid and acid fuchsin; Unna's alkaline methylene-blue and eosin; Weigert's myelin-sheath stain; and Pal's modification of this followed by acid fuchsin; and according to Marchi's method.

Sections at the level of the third cervical segment showed marked dilatation of the blood-vessels of the pia, and of the anterior and posterior nerve roots. Numerous dilated blood-vessels are found throughout the cord, both in the white and in the gray matter, and also numerous hemorrhages in all parts of the cord, many of them in the white substance and of considerable size. These radiate in many cases from the gray matter of the cord toward the periphery. Throughout the white substance there is seen a large number of enormously swollen nerve fibres, staining homogeneously with hematoxylin, and there is also considerable edema. This condition is in general more marked near the gray matter of the cord, and is seen in both the posterior, lateral and anterior tracts; still a considerable number of these swollen fibres are seen at the periphery, notably in the lateral tracts. Throughout the posterior horns there are extensive hemorrhages, while the anterior horns are almost completely destroyed by hemorrhage, especially the lateral horns and the outer portion of the anterior horn, where none of the normal structures can be made out. Here and there among the mass of red blood corpuscles are seen irregularly oval masses staining homogeneously with hematoxylin, which are evidently remains of nerve cells. In the area of hemorrhage there is a moderate number of cells, chiefly leucocytes with vesicular polymorphous nuclei and a few large phagocytic cells with small more deeply staining nuclei. Many of these cells are filled with dark brownish pigment, and a considerable amount of this pigment is seen lying free. In some of the perivascular lymph spaces in the neighborhood of the hemorrhagic areas are numbers of leucocytes and phagocytic cells loaded with pigment. The sections stained by Marchi's method show that these cells have taken up a considerable amount of degenerated myelin. There is also a considerable amount of degenerated myelin throughout the section, not more marked in one part of the cord than in another. The myelin sheaths of many of the enormously swollen fibres spoken of above show as thin black or grayish lines surrounding the swollen axis cylinder.

Sections from a little above the first level show much the same condition except that the hemorrhages in the white matter are few and small, and the hemorrhages in the posterior horns are smaller, and a portion of the inner border of the anterior horn has escaped destruction, at which place a few nerve cells can be seen which are fairly normal.

Sections from about the level of the seventh cervical segment show great dilatation of the blood-vessels of the gray matter of the cord. There is also a small hemorrhage at the tip of the right anterior horn. In the middle of the left posterior column is a circular area, which is very edematous, and contains a great many enormously swollen nerve fibres, and quite numerous leucocytes filled with dark reddish-brown pigment. Here also there is dilatation of the blood-vessels of the nerve roots and the pia. Sections stained by Marchi's method show a diffuse fatty degeneration of nerve sheaths and axis cylinders in all parts of the cord, though most of the fibres are unaffected. There is also a well-marked degeneration of the nerve roots, the anterior and the posterior ones being about equally affected.

Sections from various levels of the cord stained by Weigert's and Pal's methods show no degeneration of the ascending or descending tracts. There are no hemorrhages in the pia.

[1] From the Pathological Laboratory of the Boston City Hospital. — Read before the Boston Society for Medical Improvement, May 8, 1899.

Summary. — This cord showed at the level of the third cervical segment a narrow area where there were almost complete destruction of the cord, complete destruction of the gray matter, by hemorrhage, and very numerous and large hemorrhages in the white substance, with destruction of some fibres and marked swelling of many of the remaining fibres, damage which was probably sufficient to cause nearly complete interruption of conduction in the fibres which had not been torn. The hemorrhage in the gray matter had extended upward and downward, chiefly in the anterior horns, for a distance of about half a centimetre, and areas of hemorrhage or remains of hemorrhage were seen at quite a distance from the part of the cord which had been crushed, one especially in the anterior horn as low as the seventh cervical segment. There was also a moderate diffuse degeneration of nerve sheaths and fibres throughout the cord, to about the same extent in the anterior, lateral and posterior tracts both above and below the injured area, and a degeneration, moderate in amount, of the fibres of both anterior and posterior nerve roots, though not as marked as in the first case. This case, like the first one, showed no signs of secondary degeneration of ascending or descending nerve tracts, and probably for the same reason, and there were also no hemorrhages seen in the pia.

The consideration of these cases of injury of the spinal cord brings up several questions of importance. In both the greatest damage to the cord was evidently caused by compression, probably produced by displacement of one vertebra upon the other, though accompanied in the first case by fracture, as frequently happens. Certainly the narrow area of softening in the second case could have been produced in no other way than by direct compression. In this case no fracture of the bodies of the vertebræ could be made out at the autopsy. In the first case the compressed portion of the cord was greater, and more fractures of the vertebral bodies were present. In neither case was there any pressure directly upon the cord found, either from fragments of bone or from hemorrhage. This was also true of the case reported by Dr. Courtney and myself, and in the three other autopsies at the Boston City Hospital on cases of fracture of the spine in the cervical region. Thus we see that in all the six cases of fracture of the spine in the cervical region which have come to autopsy at this hospital since 1881 there has been no instance of pressure from either hemorrhage or fragments of bone. The pathological changes found were in both cases those of a myelomalacia, with hemorrhages, probably the direct results of the pressure which is produced at the time of the accident. That the cord is not found compressed at the autopsy is because of the ease with which the dislocation is reduced either ante or post mortem, a point to which attention has been called by Thorburn, Kocher, Wagner and Stolper, and others. No fractures of the substance of the cord were seen, though in the first case the softening, as is often the case, was excessive, and the cord was exceedingly difficult to handle even after hardening. Certainly judging from the sections of the three cases of injury of the cord from fracture of the spine which I have made, the case reported by Dr. Courtney, and the two reported in this paper, I must look with suspicion upon such changes as have recently been reported by Dr. Taylor. Hemorrhage as a cause of pressure was not found in any of the six cases referred to, and must certainly be rare, and probably cannot be diagnosticated except when of the gravescent type. In these three cases there was extensive hemorrhage into the substance of the cord, which in the two cases now under consideration extended in the gray matter of the cord both above and below the area of crushing. The presence of these areas of hemorrhage in cases where there has been direct injury of the spinal cord shows that the direct effects of the crush are not the only conditions with which we have to deal, and the chance of hematomyelia following trauma makes the possibility of relieving the symptoms by operation much smaller. It seems somewhat doubtful, however, whether this condition is primary, as Bailey has claimed, but certainly these hemorrhages are found after trauma, and that, too, in the less severely injured cases, though it seems more likely that they are due to direct injury to the cord in most cases rather than to any possibility that the cord, with intact vertebral column, can be stretched to a sufficient extent to produce these hemorrhages. These hemorrhages into the substance of the cord, as is well known, are more apt to occur in the gray matter, though cases are reported in which they have been found in other locations. They frequently extend for a considerable distance above and below the crushed portion of the cord. Probably these hemorrhages varying in extent in the two sides of the cord explain the often observed fact of different levels on the two sides of the body of the upper border of altered sensation.

Another point of interest in these cases is the absent knee-jerk in the first case, and the much diminished reflexes in the second one. This fact of the loss of the reflexes, especially the tendon reflexes, — for the superficial reflexes more often vary, particularly the plantar reflex, — in cases of serious injury of the spinal cord has attracted great attention, and many explanations have been brought forward. This loss was first spoken of as a constant symptom in cases of complete interruption of conduction in the spinal cord in 1882 by Bastian. He attempted to explain this as due to the interruption of tracts from the cerebellum and brought forward the supposed antagonism of the cerebrum and the cerebellum to explain various phenomena in a very ingenious way. Bruns, in Germany, accepted Bastian's conclusions and facts, but hesitated to produce any theory in explanation. Since that time many writers have taken up the subject, each showing more ability in opposing fatal objections to the theories offered by his predecessors than in himself offering any sufficient explanation. Stieglitz rejects Bastian's theory as not sufficient, and thinks that the degeneration of nerve fibres requires time, and that during this period conduction is still present, and that this degeneration of fibres inhibitory of the knee-jerk acts as an excitation of these fibres, and hence has an inhibitory influence, because of the specific energy of nerve fibres. He thinks this action is easier to understand because this inhibition from the higher centres probably acts through local inhibitory centres in much the same way that the vagus acts upon the heart. Herter and Sternberg explain this phenomenon by much the same mechanism, but adduce as the irritant the crushed portion of the cord, acting upon the upper end of the lower uninjured cord. Fraenkel thinks

the absence of the knee-jerk can only be explained by assuming an arc to the brain, the ascending limb of which he places in the tract of Gowers, but it is difficult to imagine a constant stimulation of this arc from the periphery, nor can Fraenkel satisfactorily explain that the time interval involved in the production of the knee-jerk is too short for the transmission of any impulse to the brain and back to the muscle. Gerhardt explains the phenomenon by an inhibition similar to that in traumatic epilepsy. Egger ascribes it to a functional disturbance which in time can lead to an organic lesion of peripheral nerves and muscles, which produces the permanent loss.

Whatever the explanation, the fact remains certain that in a large proportion of cases of serious injury to the spinal cord in the cervical or upper dorsal region the knee-jerks are lost, and often permanently. This, however, cannot be assumed as evidence in itself of a total transverse lesion of the cord, as too many cases have been reported in which the knee-jerks have been increased, either throughout the disease or in its later course, when examination of the lumbar cord showed it to be normal, as the case reported recently by Senator, and by Fürbinger, though in the latter the examination was not reported fully. Bischoff analyzes a number of cases from the literature and attempts to prove that in cases of total transverse lesion the reflexes may be either absent or increased, and that, conversely, with partial lesion either condition may be present. Bruns, however, has subjected these cases of retained knee-jerk with complete transverse lesion of the cord to a merciless criticism, and rejects them all. Bischoff calls attention also to the fact that operative experiments upon the cerebellum, tumors, and cases of atrophy of the cerebellum all tend to show that the action of this organ upon the knee-jerk is rather inhibitory, and that therefore destruction of paths from the cerebellum would tend to cause the increase of this reflex. He finally concludes that the cause of the loss of knee-jerk in these cases must be a local one, and that this must be in the peripheral nerve, and ascribe it to anemia produced by circulatory changes resulting from the shock of the accident. We have not spoken of shock as a cause of the loss of the reflexes, as that could only be a temporary cause, while the loss is more often permanent. As Bruns was the first, so he has remained almost the only one who has published a case in which the lumbar region of the cord, the peripheral nerve, and the muscles have all been examined carefully, though at least half a dozen other cases, as Senator's second case, have been reported where a sufficient examination of the lumbar cord has been made, to afford a firm basis for Bastian's claims. Van Gehuchten has recently clearly stated the conditions of loss of the reflexes. The muscle tonus is only the expression of the continuous stimulation of the motor cells of the anterior horn, which is produced by the other neurons in relation to which the cell is placed. These neurons are:

(1) The fibres of the posterior nerve roots.

(2) The cortico-spinal pyramidal fibres.

(3) The descending cerebellar-spinal fibres.

(4) The fibres of the posterior columns, arising chiefly from the mid-brain. These descending fibres lie in the comma tract of Schultze, and in the borders of the antero-lateral tracts.

The pyramidal fibres have an inhibitory influence. The posterior nerve roots bring a certain amount of stimulating influence, while the cerebellar fibres, and the posterior descending fibres act apparently energetically as a stimulating influence. Hence the loss of reflex movements can only recur under three conditions:

(1) An anatomical or functional interruption at some point of the reflex arc.

(2) From an abnormally strong inhibitory action upon the motor cells, as from shock.

(3) By a diminution of the nervous tone of the cells of the anterior horn below a certain minimum, as occurs in transverse lesions of the cervical and upper dorsal cord, and occasionally in partial lesions.

The first of these two patients lived eight days, and so the loss of the reflexes in this case cannot be ascribed to shock, but it is possible that this may have been a cause in the second case, where death took place upon the third day. While I cannot advance an explanation of the disappearance of the reflexes in severe transverse lesions of the upper part of the spinal cord, I wish to call attention to the fairly well-marked degeneration of both posterior and anterior nerve roots in all three of these cases examined by me, as shown by the use of Marchi's method, which has been used, so far as I have been able to find, only by Bischoff, though in this connection I wish to call attention to the changes in the structure of the cells of the anterior horn recently described by Marinesco. The presence of these changes and degenerations is in favor of the theories of Egger and Bischoff, and that such changes should occur at a distance from the actual lesion cannot surprise us when we consider the marked circulatory and nutritive changes which accompany severe injuries of the spinal cord, as shown by the marked sweating so often seen. It seems probable, therefore, that in these cases of total interruption of conduction in the spinal cord in its upper regions we have to do in different cases with different causes for the abolition of the reflexes. In cases of fracture with severe crush of the cord, in addition to factors which come into play in the cases of destruction of the cord by slow compression, there are often the functional and degenerative changes in the reflex arc itself, probably produced by the changes in circulation, and this may be operative in the cases of partial destruction of the cord, where conduction has been lost for a time after the injury, without absolute interruption of the continuity of all the fibres in the cord. Such an explanation, however, will not suffice for the case of Bastian, more than once referred to by Bruns, in which the knee-jerks were absent at times and present at others, always appearing and disappearing with changes in the sensation, which were always completely abolished when the knee-jerks were absent, and returned with their return. Here we must, I think, assume disturbances of conduction of fibres from the cerebrum and cerebellum, and no more satisfactory explanation has yet been given than that first brought forward by Bastian, and by Jackson, and recently by Van Gehuchten. We have at all events in this loss of the knee-jerk an added symptom from which we may infer a severe injury of the upper portion of the spinal cord.

Cases of fracture or dislocation of the spinal column are probably more frequent than is generally supposed, as many of them are slight, and in these the spinal cord escapes or is only very slightly injured, as

we see in many of the cases reported by Kocher, and by Wagner and Stolper.

We cannot take up in so short a paper the various forms of injury of the spinal column in detail, but the method of production is of importance, and these are of three chief classes.

(1) Direct crushing blows upon the arches of the vertebræ.

(2) Falls upon the head or buttocks, usually producing a crush of the bodies of one or more vertebræ.

(3) Forced flexions, or more rarely extensions, of the spine, producing dislocations, with or without fracture, which are usually of the bodies of the vertebræ, and of the articular processes only.

The question of treatment of these injuries is of course the most important one with which we have to deal, and in regard to this our conclusions will vary with the conditions present. In the cases of no injury or only slight injury of the spinal cord the problem is a comparatively simple one. The normal relations of the bony parts must be restored by manipulations or operation, or both, so far as is possible, due care being exercised to avoid injury of the spinal cord. Where the cord has been seriously injured, as is unfortunately frequently the case in the fracture-dislocations of the cervical region, we should endeavor to ascertain the extent of this damage, and the question arises whether we are able to do this. I think we can certainly answer this question in the affirmative, as Herter did in 1891. It is on the following factors that we must base our opinion as to whether we have a total transverse lesion of the cord or a partial one. The first point which influences our decision is the history of the onset of the symptoms, whether sudden and at once, or gradual and after an interval, the first being seen in the cases of complete crush. Then in these cases the motor paralysis is complete and generally of the flaccid type, while in the partial injuries it is more apt to be partial, and accompanied by muscular spasm. The same condition of complete or partial impairment of sensation in these two classes of injury is also seen, and we should include all forms of sensation, not neglecting that of localization, which Fraenkel believes to have a close relation to the knee-jerks. The condition of the reflexes also affords us aid, as they are more apt to be abolished in the complete transverse lesions, though this is somewhat variable, and particularly so in regard to the plantar reflex, which is often retained when the remaining reflexes are lost. The complete paralysis of the sphincters of the bladder and rectum again points to a severe injury of the cord, but here we should guard against considering the ability of the bladder to retain a certain amount of urine as an indication that it is normal, a point to which Thorburn and others have called especial attention. In paralysis of the bladder there remains a certain amount of tonic contraction of the sphincter, and this permits the bladder to become filled, when the urine escapes not by dribbling, but in considerable quantities, the discharge often being brought about by a change of pressure, as in changing the position of the patient. Again, priapism is more common in the severe injuries of the cord, as is also the severe sweating, and the involuntary muscular twitchings in the paralyzed muscles. On the other hand, pain is more often present in the partial lesion, meaning by this symptom, of course, spontaneous pain in the paralyzed limbs. Most important of all, perhaps, in enabling us to decide that the lesion is only a partial one are variations in the symptoms of paralysis, loss of sensation and others, which show that conduction through the injured portion of the cord has not been entirely lost.

From these symptoms, then, we can draw conclusions as to the condition of the spinal cord, and I know of no one who has claimed to be able to produce favorable results by operation on cases of total crush of the cord. It is then only in cases where the lesion of the cord is a partial one that we can hope for relief, though it is sometimes claimed that the chance of the interruption of conduction being produced by pressure upon the cord warrants us in operating upon even apparently hopeless cases. A careful study of a large number of cases reported by Wagner and Stolper, and Kocher, as well as from the literature in general, shows us that this condition is extremely rare either from hemorrhage or from fragments of bone. The cases in which pressure from fragments of bone exists are practically limited to those in which the arches of the vertebræ are crushed by direct violence. In other cases the strong anterior ligament is seldom broken, and this prevents fragments of the bodies of the vertebræ from pressing upon the cord, so that nothing can exert pressure except the continued displacement of one vertebra upon another, and this is produced in the large majority of cases by forced flexion of the spinal column, and is usually remedied by hyperextension of the spine, perhaps aided by slight extension, followed later by fixation in some manner, in all cases where the bones have not already resumed their normal position when the patient is first placed upon his back by bystanders or others. The only class of cases then that remains in which operation offers any hope of aid are, as Thorburn concludes, those in which the arches have been crushed by direct violence, either by blows upon the back, bullet wounds, or the way in which the patient has fallen. In these cases, and practically in these cases alone, have we a reasonable chance of finding continued pressure upon the spinal cord, and relieving it by operation, though even here the final result must depend upon the damage done to the cord, for the estimation of which I have tried to give the indications in this paper. In conclusion, I can only state that in all cases of injury of the spinal column severe enough to injure the cord, we are unfortunately apt to find that irreparable injury has been done to the cord, either from hemorrhage into its substance, or complete crush of it, so that the prospect of relief of symptoms of these cases by operation is slight, and we can only sorrowfully say in regard to this field of surgery of the spine, as Brissaud does: "Je reste convaincu que la chirurgie de la moelle épinière est pleine de promesse, comme l'enfer est pavé de bonnes intentions."

GROWTH AND SOCIOLOGICAL CONDITIONS.

BY ARTHUR MACDONALD,
Specialist in the United States Bureau of Education, Washington, D. C.

THE following investigations in juvenile anthropometry show experimentally the influence of sociological surroundings upon the growth of children.

Further demonstration of the influence of such conditions can be found in a work [1] (by the writer) published by the United States Bureau of Education.

Influence of unfavorable conditions on the life and physical development of youth is shown in the following table of Pagliani:

TABLE I.

Number of persons.	Age. Years.	Average weight. Kilogrammes.	Average height. Centimetres.	Average chest girth. Centimetres.	Average lung capacity. Cubic centimetres.	Average muscular force. Kilogrammes.
9	10	24.51	126.3	61.0	1,660	66.5
34	11	26.18	128.1	61.2	1,700	68.5
45	12	28.38	132.1	62.8	1,860	79.0
41	13	31.75	137.5	65.2	2,045	95.0
29	14	33.06	140.0	66.4	2,100	105.0
23	15	39.36	148.6	69.5	2,445	118.5
15	16	41.47	151.2	70.3	2,485	121.0
9	17	43.20	151.3	71.6	2,660	136.6
6	18	44.55	154.3	72.6	3,115	142.6
4	19	46.65	156.0	74.2	3,128	150.0

These measurements were made on the inmates of an institution in Italy.

In Table II by Weissenberg the number in some of the groups is not large, but the figures show a general regularity.

The poor are less in height and weight than the wealthy classes.

INFLUENCE OF POVERTY ON NUTRITION.

In Table III Vazhnoff shows the influence of unfavorable conditions on nutrition among Russian children.

DEGENERATION OF GROWTH.

According to Liharzik, growth is regular, and all deviation tends to produce disease, as disease also produces deviation. A large head is frequently accompanied with a contracted chest; here mental action may be slow — probably from deficient supply of purified blood. Boys of small frames often have rather large heads and are deficient in repose of character. City-bred children are usually more vivacious, but

[1] Experimental Study of Children, including anthropometrical and psychophysical measurements of Washington school-children; measurements of school-children in United States and Europe; description of instruments of decision in the laboratory of the Bureau of Education; child study in the United States; and a bibliography. individuals. In Table IV is shown how the growth degenerates as we go lower in the social scale: there is a difference of five inches in average statures between the best and worst nurtured classes in the community.

From this table will be seen the relative statures of

average heights and weights at different ages are shown in Table V.

Comparing the poor with the well-to-do classes, the results show that for boys of the same age the height varies from 0.7 to 4 centimetres in favor of the well-to-do classes; for girls it varies from 1.7 to 4.1 centi-

boys of the age of eleven to twelve years under different social and physical conditions of life. The zigzag line running through the means shows the degradation of stature as the boys are further and further removed from the most favorable conditions of growth.

metres in favor of the well-to-do. The children of the well-to-do classes excel also in weight for the same age; for boys the excess runs from 0.3 to 4.7 pounds; for girls from 1.6 to 4.6 pounds. In general the difference between the classes is not so great as in other places, as in Freiburg and Turin, except in Boston,

where the difference between the classes is less marked.

Hasse also gives data concerning the weak or defective children, who generally cannot attend school regularly. Such children are usually abnormally developed or have some chronic ailment. In the primary schools nine per cent. belonged to this class. A striking fact is this, that in many cases these children in certain years were over normal; that is, were taller and heavier than other children. This suggests that there is a certain normal relation between mental and physical development, the finding of which is one of the aims of anthropometry.

A PENSION FOR A DISTINGUISHED PHYSICIAN. — According to the *Lancet* for August 5th, her Majesty's government, on the recommendation of the governor-general of India in council, has conferred on the distinguished physician Sir Joseph Fayrer, as a reward for distinguished and meritorious service, a pension of £100 per annum.

Clinical Department.

AN EXTERNAL APPLICATION IN SCARLET FFVER TO SHORTEN THE PERIOD OF DESQUAMATION AND DIMINISH THE DANGER FROM IT.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

IT is thought that scarlet fever is disseminated in part by means of the epithelium which is shed during desquamation. To prevent the spread of the scales during this time an application should be made to the skin and we can choose one that combines several qualities. It should be harmless to the patient, sticky enough to diminish the mechanical dissemination of the peeled skin and yet promote its removal and hasten the return of this organ to a healthy condition, and also have some germicidal properties. I have found glycerin mixed with hydrogen-dioxide solution containing a little free hydrochloric acid, which latter contributes germicidal properties to the mixture, to answer this purpose; one part glycerin to seven parts of a ten-volume hydrogen-dioxide solution. If the amount of hydrochloric or nitric acid in the dioxide solution is very small more may be added, but if the solution contains one-twentieth to one-tenth of one per cent. it will probably have considerable germicidal action if in contact with the scales for some time.[1]

Several years ago, in the scarlet-fever wards of the Boston City Hospital, I demonstrated that the period of desquamation could be shortened by the use of this mixture. The method which I used may be briefly described by quoting from a paper which I

[1] It should not be brought in contact with colored fabrics.

published in the *American Journal of the Medical Sciences*, August, 1895.

"In scarlet fever it seems to me desirable to prevent the dissemination of the epithelial scales which are often shed abundantly, and to hasten the removal of the layer of epithelium in order to free the normal skin. For this purpose I have the patient rubbed all over daily — avoiding the hair — with a mixture containing seven parts of ten-volume hydrogen-dioxide solution and one part of glycerin; if the patient finds this too sticky, the proportion of glycerin may be reduced. A quarter of the body may be done at a time, and some hours later another quarter and so on. As soon as any portion of the skin is normal the application may be there dispensed with." The average length of the period of desquamation may be reduced if this treatment is properly carried out. To shorten this period is desirable in private practice and in a hospital it has a money value. Take, for example, 1,000 cases; if this treatment will shorten the stay of the patients only three days (I found the average more than this) we have a total of 3,000 days, or eight years, saved.

Medical Progress.

REPORT ON PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

(Concluded from No. 10, p. 241.)

OPEN DUCTUS BOTALLI.

THE comparative frequency of cases of congenital cardiac defect persisting without essential impairment of development or marked circulatory disturbances, is again illustrated by two instances of open ductus Botalli reported by Burghart[7] and Drasche.[8] Both patients were adults, twenty-one and twenty-eight years of age, and neither showed anything of special significance in previous history or general examination; there was no cyanosis or evidence of defective blood supply.

In the first case there was visible pulsation in second intercostal space to left of sternum, apex beat strong and heaving just outside nipple line (space not stated), dulness from upper border of fourth, extending toward right as far as mid-sternum; above this dulness, however, was a "ribbon-shaped" area of dulness two and one-half to three centimetres broad, running upward near left sternal border; in the second left intercostal space was felt a strong thrill which seemed transmitted up and to the left, but could be felt everywhere over precordial area; in the second left space a sharply localized murmur occupying systolic interval and extending into diastole; no second sound except after rest in bed; murmur plainly heard ten centimetres from body; aortic sounds masked by pulmonic murmurs which were also heard in left interscapular region. From above facts, observer concludes that ductus was open, but he infers that there was probably also pulmonary stenosis.

In the second case pulsation was visible in the second and fifth intercostal spaces and a thrill palpable in second and third; apex in fifth, heaving; dulness beginning in second space and extending to right one centimetre beyond left sternum border; at apex systolic murmur, second sound pure; in second left space a peculiar systolic murmur of marked intensity; second sound somewhat accentuated and followed by a soft murmur; the systolic murmur at times quite rough and "whirling," loudly transmitted to carotids; over aortic area a systolic murmur and faint second sound. At autopsy (death due to caustic-potash poisoning) was found a small, thin-walled heart; the aorta and pulmonary artery touched each other at site of ductus Botalli, through which could be passed a probe three millimetres in diameter; through foramen ovale could be passed a bristle only. It was assumed that both systolic and diastolic murmurs were due to stream of blood pouring into pulmonary artery from aorta, where pressure is at all times greater.

The important diagnostic signs are considered to be a systolic murmur of extraordinary intensity, variously described as rasping, whirling, rustling, buzzing, or even musical, heard loudest in first or second left intercostal space, where also generally pulsation is visible and a thrill palpable; diastolic murmurs are less often heard. The area of heart's dulness is somewhat increased and Gerhardt describes as characteristic the ribbon-shaped area of dulness in the first and third space, corresponding to the dilated pulmonary artery.

[7] Deut. med. Woch., 1898.
[8] Wien. klin. Woch., 1898.

ACUTE ENDOCARDITIS.

Harbitz[9] has made a careful study of all the cases of endocarditis which have come under his observation during the past four years. Forty-three of these were classed as infectious, of which seventeen were due to the streptococcus, five to the pneumococcus, eight to the the staphylococcus and three to other specific organisms. In addition there were ten cases of healed infectious endocarditis. Although due to the ordinary pyogenic bacteria they differed so markedly both in the pathological appearances and clinical history, that a division into two groups is fully justified. The first is represented by those classes whose point of origin is found as a rule in some local collection of pus and which run a rapid course as a fulminating pyemia with high fever. At the autopsy a diphtheritic membrane is usually found in the valves as well as ulcerative and necrotic foci in the valvular substance, and occasionally at their bases abscess cavities are seen running deeply into the cardiac muscle. At the same time multiple abscesses are found as a rule in the skin, heart, spleen, kidneys, eyes, etc. These cases illustrate the classical description of malignant endocarditis and most commonly result from infection with the pyogenic staphylococci.

In the second group, due chiefly to streptococci or pneumococci, the inflammation of the endocardium does not appear as one symptom of a general infection, but rather as the central focus from which the infection was spread. A striking feature is their long duration, four, six or even ten months elapsing between the appearance of the first symptom and the death of the patient. The onset of the disease is gradual, the first symptoms consisting of slight fever, rheumatic pains and malaise, which gradually give way to more serious manifestations, dyspnea, cough, hemorrhages, cyanosis and edema. Fever may be slight throughout, or it may be remittent or intermittent. Symptoms connected with the kidneys are often so pronounced that clinically the case is regarded as one of

[9] Deut. med. Woch., February 23, 1899.

hemorrhagic or parenchymatous nephritis. Pathologically, destructive changes, ulcerations or abscesses, are rarely found, nor does a cellular infiltration or necrotic foci appear in the neighboring valvular tissue. The process, as a whole, appears to be an old one in the stage of organization, that is, it shows a tendency to cure. In these cases there are no pustules or abscesses in the skin, kidneys or heart, and no infected suppurating infarctions. The numerous infarcts in the kidneys and spleen are pale and dense, and the foci of softening in the brain are not suppurating, although the emboli causing them were detached from vegetations from an infectious endocarditis, loaded with bacteria. The kidneys are in a condition of acute or subacute parenchymatous or hemorrhagic nephritis. Bacteria are rarely found and the cause of the condition is probably a toxic one, secondary to the endocarditis; no rigid line can, however, be drawn between the two classes, since some cases due to streptococci or pneumococci run an acute course, while cases due to the staphylococcus may, though rarely, run a chronic course. They may also approach each other in their other clinical symptoms as well as in their pathological appearances.

Among the non-infectious cases of endocarditis he examined six occurring in acute rheumatism, in all of which a crop of small, warty excrescences was found along the line of closure of the valves, but never ulcerative or diphtheritic patches. Bacteria could not be demonstrated even by culture. These negative results were of interest since they failed to demonstrate either the microbes which have been claimed to be specific, or the attenuated forms of the ordinary pus products to which etiological importance has been ascribed. In nine cases of tuberculosis warty or polypoid growths were found in the valves, but the cultures were sterile in them all. In one instance a few tubercle bacilli were found in a cover-glass preparation, and in two others guinea-pigs died after inoculation with the valvular excrescences, but the causal relation between the endocarditis and the tubercle bacilli is very doubtful.

He has also found in other diseases, Bright's, carcinoma, etc., excrescences in the line of closure of the valves, without being able to discover any bacteria, so that it still remains to him an unsolved problem, whether to ascribe them to one or more infectious agents or to a form of chemical action from abnormal metabolism.

VESICAL ASTHMA.

Under this head Pawinski[10] reports several cases of paroxysmal dyspnea occurring in elderly men whose enlarged prostates had led to the accumulation of residual urine in the bladder. In every case there were changes in the circulatory and respiratory apparatus, such as arterio-sclerosis and emphysema. They were usually, however, to be regarded as incidental to age rather than as real pathological conditions, although in a few the pathological changes were more marked, as shown by the presence of a chronic myocarditis or valvular lesions. Treatment of these conditions failed to cure, while the effects of catheterization were so conclusive that it was impossible to doubt that retention was the cause of the trouble. He lays much less stress on reflex action than on auto-intoxication in explaining this relationship, as he believes the latter to be responsible in a majority of cases, from the similarity of the symptoms to those accompanying other cases of self-poisoning; a bladder wall which is no longer sound, owing to the prolonged retention of urine, being capable of absorbing toxic substances.

[10] Rev. de Méd., March 10, 1899.

BRONCHITIS AND ARCHITECTURE.

Gee[11] says, in conclusion of the Lumleian Lecture on bronchitis and allied disorders, that it is highly probable that most catarrhs are due to a specific infection and are often dependent on contagion from man to man. The means of prevention are therefore to be found in ventilation and cleanliness, if, indeed, ventilation is not a form of cleanliness. Patients catch their catarrh either in badly ventilated houses or in buildings where men most congregate, especially in offices, shops and churches. Large shops, museums and libraries are purposely unventilated to prevent the injury of their contents by dust or smoke, while churches are never properly aired because their architecture does not admit it. The revival of Gothic architecture has been, from the sanitary point of view, a great mistake, and modern dwellings are no better than the churches. In domestic sanitation people have fixed their attention too exclusively upon drainage and the water supply; light and air are not reckoned. The well of the staircase ought to be a reservoir of pure air and to have an independent supply from without, yet in most houses it is ventilated only through the rooms, in fact is not ventilated at all, while the rooms themselves are not much better off. The subsidiary and merely ornamental arts, which do no more than please the eye, are studied to the neglect of that far greater art which promotes the happiness and welfare of the whole man, the art of preserving health.

[11] Lancet, March 18, 1899.

DISPLACEMENT OF THE HEART IN PLEURAL EFFUSIONS.

From a careful study of a number of cases of pleural effusion by percussion, auscultation and the radiograph as well as by experiments on the cadaver Carrière[12] arrives at the following conclusions: In left-sided effusions cardiac displacement almost invariably occurs, but if the effusion be less than one litre and more than 700 grammes the apex maintains almost its normal situation, save that in the vertical position or in the right lateral decubitus it is lowered from two to four centimetres and tends to approach the median line. When more than one litre has accumulated the heart is so displaced that its long axis tends to become vertical, while the apex is lowered and moved toward the right, until in the presence of two and a half to three litres it is found in the neighborhood of the xiphoid cartilage. With more than three litres of fluid present the heart is moved *en masse*, together with the mediastinum, toward the right, but it remains vertical with the apex near the xiphoid. Twisting of the heart on its axis is never observed.

In right-sided effusions under one litre there is no cardiac displacement, except that with the patient in the vertical or left lateral position the apex is displaced two to four centimetres to the left; with more than one and less than three litres present the apex is displaced from three to eight centimetres. With larger amounts the displacement does not exceed ten

[12] La Presse Méd., December 17, 1898.

centimetres. Double effusions lower the heart *en masse* and tend to straighten its axis.

DISPLACEMENT OF HEART IN PLEURISY.

Pitres[13] in a short note says that he has been led to the somewhat paradoxical conclusion that displacements of the heart in pleurisy, far from being a source of danger to the patient, should be regarded as a providential proceeding to protect the central organ of circulation from the increased intrathoracic pressure. A pleural effusion exercises an eccentric pressure in all its surroundings, while the mediastinal displacement has the effect of moving the heart *en masse* and not by a movement of rotation on its axis, which is anatomically impossible. The acting agent in protecting the heart is the pericardium with its solid attachments above and below. An effusion into the pleura lowers the diaphragm, which draws in the pericardium, rendering it tense and vertical, thus displacing the heart and giving an opportunity for the auricles to function, etc. In a bilateral pleurisy this mechanism is not possible, hence its danger.

Reports of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

TWENTY-FIRST ANNUAL CONGRESS, HELD IN CHICAGO, MAY 22, 23 AND 24, 1899.

FIRST DAY.— MORNING SESSION.

PRESIDENT'S ADDRESS.

THE President, WILLIAM E. CASSELBERRY, M.D., of Chicago, delivered the following address:

The honored custom of an address from the chair affords opportunities for suggestion looking to the welfare of our organization and of the department of medicine which it represents which would not find expression in any set paper or formal discussion. I think all are conscious of the change in the drift of laryngological practice wrought of recent years, first, by the evolution of nasal pathology, and secondly, by the appropriation of the ear. From a physician treating affections of the throat and chest, the laryngologist is fast becoming a surgeon with a routine of practice limited to local measures as applicable to the upper respiratory tract alone. While freely conceding progress has been realized along local surgical lines I deprecate the tendency of the day to deal with the throat and nose exclusively in a mechanical way as if they were organs detached. I believe it engenders narrowness of thought, and that, through habitual disuse, there is gradually lost to the physician much of that fundamental knowledge of pathology and applied therapeutics which is so essential to the welfare of the patient. There are now nasal enthusiasts whose idea of the subject entire seems to consist in the establishment of a wide patency of the nostrils.

The intimacy of the ear with the throat and nose is conceded. The laryngologist has the treatment of aural affections actually thrust upon him. Even the patient's discernment convinces him that the laryngologist's skill and equipment are the means best adapted to the end. And having appropriated the ear one should cultivate an exhaustive knowledge of the organ, but as an addition to laryngological lore, not as substitute for a part thereof. Aural enthusiasts have developed among laryngologists whose commendable studies of the ear have been a help but who centre their attention so forcibly upon that organ as to convey the impression of neglect of fundamental laryngological precepts.

Add to these our *confrères* in smaller towns who find it expedient to group together the eye, ear, nose and throat and we encompass numbers who to-day are posing as laryngologists whose education, interests and restricted routine of practice put them out of touch with important medical and systemic phases of the subject.

Do latter-day laryngologists as a class habitually endeavor to establish the real diagnosis in the earliest demonstrable stage of pulmonary tuberculosis? Are not such patients liable to come first before us with their irritable throats, hacking cough, tendency to hoarseness and inclination to rhinitis?

It is not claimed that the laryngologist must of necessity embrace in his practice all pulmonary diseases — that is a matter of choice and expediency; but it is urged that he be ready to apply all the arts of diagnosis and that he be conversant with every resource known to medicine in the treatment of pulmonary conditions for the benefit of cases of laryngopulmonary tuberculosis, laryngobronchitis, bronchial asthma in association with ethmoiditis, and other conjoined pathological conditions of the upper and lower respiratory tracts.

Nor will it answer to omit attention to the heart, aorta and mediastinal contents. Paralysis of a vocal cord through pressure on the recurrent nerve by an aneurism is a simple proposition, but more complicated ones which require a high degree of diagnostic skill are continually encountered.

Regarding the treatment of pulmonary conditions, especially tuberculosis, cases which are not complicated by affection of the throat are naturally claimed by the department of internal medicine. It is not possible, nor even desirable, to draw an absolute line at this point between laryngology and internal medicine; in practice they are bound to overlap, but conceding that if drawn anywhere it would be here, there remains a considerable proportion of pulmonary cases in which the upper respiratory tract is so far implicated that they fall naturally under the care of the laryngologist. Hence, as before said, he should be conversant with every resource known to medicine in the treatment of pulmonary states. He should be a good systemic therapeutist and continue to cultivate the art of prescribing, realizing the uses as well as the limitations and abuses of internal medicine. Above all, one should study the conditions of natural immunity and susceptibility in order that having made an early diagnosis one may direct the mode of life and place of abode best adapted to arrest the disease and overcome the susceptibility. This implies a ready familiarity with sanitation, hydrotherapy, climatology and sanitarium resources and methods. We get little convincing information concerning climatic effects upon laryngeal tuberculosis. While Heryng, Krause, Gleitsman and others have demonstrated the value of surgical measures in suitable cases of laryngeal tuberculosis, there are yet so many which are unsuitable for this line of treatment that one turns with gratification to the reports of Solly and Levy from the Rocky Moun-

[13] La Presse Méd., April 24, 1898.

tain region to find that unmistakable laryngeal tuberculosis in the proportion of 20 per cent. recovers in that climate, and that another 20 per cent. lives along indefinitely, greatly improved. Carefully studied reports from other resorts would be welcome and laryngologists at large should thoroughly familiarize themselves with the principles of climatology in order to intelligently serve their patients.

In connection with bronchial asthma, studies in nasal pathology have furnished gratifying information concerning the associated polypoid changes in the ethmoid region, and they tend inferentially to establish a vasomotor defect as the common cause of both the nasal and bronchial symptoms. Pronounced relief and often a practical cure may be effected by nasal treatment. This the laryngologist is much more likely to secure if he show himself willing and ready to assume full charge of the case, attending not only to the nasal surgery but exhausting the pharmacopeia and climatic resources to bring the fullest measures of cure or relief.

For a familiarity with bacteriologic technique there is a constant need in the practice of laryngology. The hunt for the Klebs-Löffler bacillus is already popularized. The search for the Cannon-Pfeifer bacillus of influenza and for the micro-organisms of pneumonia should be reduced to the same practical basis. "We will be raised in our esteem in the degree that we add a little more science to our art."

All laryngologists are familiar with the many throat conditions which appear as salient features of underlying systemic states and yet in the overswing of the movement toward localism general pathological data, systemic therapeutics and hygienic aids are not always utilized to the utmost. How often is edema of the larynx merely secondary to chronic nephritis, and laryngeal ictus simply the forerunner of locomotor ataxia? Indeed I might enumerate indefinitely associated throat and systemic states, but I have said enough, I think, to support the contention that the laryngologist should continue as of old to be first of all a good physician and after that something more, a specialist.

Nor need a man with this breadth of view be any less skilled in the operative technique of tonsillotomy, in the correction of deviated septa, the surgery of the collateral sinuses and the mastoid operation. He can appreciate the disadvantage of nasal obstruction just as well as another who perceives that only.

Let us profit by each other's experience, search along liberal lines and endeavor to realize Emerson's conception of power: "A cultivated man, wise to know and bold to perform, is the end to which nature works."

Dr. J. W. Farlow, of Boston, read a paper entitled

IS THE SO-CALLED "AMERICAN VOICE" DUE TO CATARRHAL OR OTHER PATHOLOGICAL CONDITIONS OF THE UPPER AIR PASSAGE?

By "American voice" is meant the characteristic nasal twang so commonly noticed in Americans. Conditions of the larynx and fauces which cause their own distinctive vocal impairment are not here considered. We do not mean by the term "American voice" the thick voice and that of low carrying power. Any condition which hinders the passage of air into the nose tends to diminish the nasal resonance, and does not contribute to the production of the nasal voice.

Where we have anterior septal deviations and spurs, the air during vocalization vibrates abnormally in the nasal chambers; so also when the nose is narrowed at the tip, and where we have anterior polyps or anterior turbinal enlargements. Frequently is seen chronic catarrhal inflammation of the mucosa without hypertrophy. From all these causes there results anesthesia and paresis of the soft palate, and some tones which should be formed in the mouth are formed higher in the nasopharyngeal space. This explains the occurrence of the nasal twang after operations for the removal of adenoids, which is apt to persist until the palate has regained the tonus lost from disuse. Atrophic rhinitis does not seem to cause a nasal voice.

It is convenient to classify our patients for purposes of this study into those up to twelve years, those between twelve and thirty, and those above thirty. In the first class the nasal voice is common, but the lesions enumerated above, which might seem to stand in a causative relation thereto, are not common. In the second class these lesions are more common than in the first class, but the occurrence of the nasal voice is not more common, and does not appear, therefore, to have any constant relation with the apparent formative causes. In the third class the nasal voice is less common than earlier in life. From the foregoing considerations, it is obvious that the nose is not the determining factor in the formation of the nasal voice, because the nasal lesions do not determine the classification into nasal and non-nasal voices. The voice can often be improved by training without any medical or surgical interference, and pathological states have more to do with the range and power of endurance of the singing voice than with the quality in the medium register. The nasal voice is more often a matter of imitation. Good public speakers and actors often have poor vocal organs from a purely anatomical point of view.

Anterior obstructions are common in all civilized races. Some of the most pronounced nasal voices are heard in country villages. In the United States the great influx of foreigners has introduced all sorts of vocal sounds into common speech, and we are quite indifferent to the best methods of speaking. Hence, children should be carefully trained in this respect — for in them imitation of the vicious vocal methods they constantly hear is the most potent factor in the production of the nasal voice. Every fall our daily papers are filled with the advertisements of singing-teachers, but for every one who aspires to sing there are one hundred who use the voice for conversation only. These latter are content to speak after the manner of the community in which they live, and no thought is given as to whether this is a proper manner or not.

Dr. G. Hudson Makuen, of Philadelphia, opened the discussion. He said that far more attention should be given to proper methods. As a rule, physicians know little about the subject. Laryngologists should instruct singing-teachers. The "American voice" is due to the excessive tension of our modern life. We should cultivate the gospel of relaxation, for our "push," so called, is fast getting to be a national calamity. The active anatomical factor in nasal voice is probably a low-hanging palate during speech. The sound vibrations are centered in the post-nasal space. We must train the levator palati muscles, which can be done by having the patient

practise several times daily with open mouth before a mirror.

DR. L. AMORY DE BLOIS, of Boston, thought that racial condition had much to do with the character of the voice. We are all familiar with the guttural of the German, the vibratory nasal French voice and the high-pitched voice of the Yankee, while the English voice, no matter what the social rank, is always of an agreeable, low pitch.

DR. JOHN O. ROE, of Rochester, said that the nasal sinuses had much to do with voice production, as they act as resonators. The voice depends on the size of the cavities and on their shape, both of which vary greatly. Anterior nasal obstruction does not cut off the influence of the resonators, while posterior obstruction does. So, also, the peculiarities of the various languages are a factor. Those who use many consonants, as Germans and Russians, have low-pitched voices, while an excessive use of the vowels, as in French, conduces to the opposite result.

DR. A. W. DE ROALDES, of New Orleans, spoke of American conversational habits, and of the fact that in the South the conventional voice tone was much lower than in the North. This might be due partly to a mixing of various race bloods in the former section, and to the lazier mode of life. The negro voice was not much addicted to tonalities.

DR. THOMAS HUBBARD, of Toledo, thought that much of our high-pitched speaking was due to the noise of our American cities, where it was often necessary to speak in a loud, high tone in order to make one's self heard. So, also, the ear becomes, from its noisy environment, obtunded to the appreciation of such misuse of the voice.

DR. FARLOW said that the low palate was often due to lack of use, but was not the original cause of nasal voice. It was secondary and not primary in its causative relation. As to the influence of the sinuses, he said that nasal voice was common in children in whom the sinuses were scarcely at all developed. English is spoken in many countries, in none of which does the voice have the same qualities as in this country. Voice is not, therefore, primarily a matter of language. As to city noises entering into the question, he had often noticed the most pronounced cases of nasal twang in country villages.

DR. JAMES E. NEWCOMB, of New York, read a paper on

ADENOCARCINOMA OF NOSE, WITH REPORT OF CASE.

Allusion was made to the fact that two cases of this nature had been reported to the Association two years ago, and that up to that time there were on record the notes of twenty-three similar cases in which the clinical diagnosis had been verified by microscopical examination. The writer's case was that of a woman aged sixty-one years of age, a widow of American parentage, who had suffered since June, 1898, with obstruction of the left naris, and almost daily nose-bleed. The latter had been severe on one or two occasions, but had never required any operative interference At times there had been a slight watery discharge with a slightly offensive odor. She had lost some flesh and strength. In September last she had blown from that side of the nose what she described as a "fleshy bean" and which was probably an ordinary polyp.

The left middle turbinate was found considerably enlarged, and the mucosa over it seemed to be in a condition of polypoid degeneration. About it were some fleshy proliferations, which bled easily upon manipulations with the probe. There were no glandular enlargements and no pressure symptoms. The masses were removed under cocaine anesthesia without incident. The report of the microscopist was adenocarcinoma. Radical interference was refused by the patient.

In looking over the literature of the subject during the last two years, Dr. Newcomb had been able to find the records of six additional cases. Cancer of the nose is relatively rare. Gurit was able to find only four cases out of a total of 9,554 cases of cancer of all organs. It is claimed that there is nothing more than coincidence between the association of the ordinary polyp with carcinoma. Tissier, who has written at length upon this phase of malignant disease, does not believe that the epitheliomatous degeneration of simple polypi has ever been definitely proven. What we know, he says, about the etiology of polypi explains their occurrence in a cancerous nasal fossa. On the other hand, Plicque states that it is pretty frequent after the ablation of numerous benign polypi, to find new polypi appearing composed this time of epitheliomatous tissue. Dr. Newcomb could hardly accept the truth of the latter statement, for polypi were very numerous and were often removed by very crude means, while the occurrence of cancer here was so rare.

Mention was also made of a surgical procedure proposed by Dr. Dawbarn. It consisted of the ligation on both sides (a suitable interval occurring between the two operations) of the eight branches of the external carotid artery and the excision of the entire trunk of this vessel in the attempt to starve the growth by shutting off its blood supply.

DR. GEORGE WOOLEN, of Indianapolis, related the history of a case of malignant disease of the nose occurring in a girl of eight years, following an injury received two years before. Nasal polypi, so-called, were removed and pronounced by the microscopist to be non-malignant and only simply mucoidal in character. Pressure symptoms were prominent. The growth was found to recur over an increasing area and the case was pronounced to be non-operable. The later clinical history clearly demonstrated the fact of malignancy.

DR. J. L. GOODALE, of Boston, mentioned a case of adenocarcinoma of the nose occurring in a man of fifty-one years. The left naris was filled with a soft bleeding mass, showing after removal and examination a fibrous stroma with epithelial cell nests. There was bulging of the eye, much pain and nasal obstruction. Removal was followed by recurrence.

DR. NEWCOMB, in closing the discussion, urged hearty co-operation and association of the clinician with the microscopist in the management of cases of doubtful nature in their incipiency.

(To be continued.)

A THIRD ATTACK OF TYPHOID FEVER. — M. Pérochaud (*Gazette médicale de Nantes*, July 22d) records a case of a third attack of typhoid fever in a man forty-eight years of age. The attack proved fatal. — *New York Medical Journal.*

THE REPORT OF THE PAUPER INSTITUTIONS TRUSTEES.

THIS document is of more than usual interest, owing to the active development which has been going on of late in the institutions of Boston devoted to the care of the dependent poor. As most of our readers know, there has been a vigorous attempt made during the last few years to raise the institution at Long Island out of the level of a mere asylum for the non-insane, but destitute and inefficient, part of the population into a position of dignity and significance from a broadly medical as well as charitable point of view. To this end, so far as the hospital side is concerned, a staff of visiting physicians has been appointed, who make medical visits as frequently as the somewhat unsatisfactory boat service permits, and whose aim it has been to establish the methods of well-organized hospital routine in the diagnosis of disease, and in the care of the patients under their charge. A training school for nurses, to which we have before had occasion to refer in these columns, has been established, and is rapidly developing into a success. Out of an almshouse hospital, with but scant medical attendance, has grown a hospital, to which the public at large and the medical profession may rightly look for practical work of a high character, and, it is hoped, later for researches of value. The opportunity in this last line, that of original scientific research, lies unquestionably in the very fact of the chronic character of the diseases there under observation. The material is there; the enthusiasm for research only is lacking, a spirit which, no doubt, it will require time and precedent to establish. In the meanwhile it is well to remind our readers that such a hospital exists near at hand, whose function it is to treat persons suffering from chronic forms of disease and to study their diseases by modern methods.

The report before us is interesting in many ways, and first from the admirable consideration of the problem of pauperism, or, in last analysis, the problem of physical and mental incapacity, which it is quite within the province of the broad-minded physician to investigate. The "rounder" question is taken up and the intention expressed of studying even more carefully than has yet been possible the manifold causes which lead to this repeated passage of certain persons through the various public institutions. Statistics of much interest are brought to bear upon the subject, but it is clearly a matter, like many other social evils, which will require a long period of painstaking study before broad conclusions may be drawn. To the physician the questions of alcohol and syphilis are all-important in this connection, for to one or the other of these two causes may certainly be attributed much of the degeneracy and incompetency everywhere observable, but particularly conspicuous in an institution devoted to the care of those who through excesses of various sorts are brought to a condition of absolute dependence. It has somewhere been remarked and is always a significant fact that the difference between the degeneracy of the pauper and of the well-born is rather one of appearance than fact. Precisely the same influences permeate society at large and it is merely chance circumstance which makes conspicuous the disgrace of the one and shields the downfall of the other. The broadly human problems which an institution like Long Island presents certainly reach from the top to the bottom of society. Because our opportunities for study are solely at the bottom in no way alters the fundamental problem. It is clearly the intention of the trustees to work out the problems which the institution offers, as a glance at their report shows. For example, the detailed histories of three families are given in the form of tables, which must be of great interest to the student of degeneracy.

Regarding this matter, the report says:

"One cannot look into the antecedents of an almshouse population without coming across some of the tangled and interwoven threads of pauper and semi-criminal and defective relationships. Three such instances are given, one of which leads back to a home in the old Crystal Palace building on Lincoln Street. It is only in retrospect that we get full sight of the ramifications from such centres of degenerate life; although they should not be accepted as representing frequent conditions, it is worth while to study them with care, so that if possible in the case of persons of similar tendencies now coming into and going out of the almshouse, through the full co-operation of all municipal, educational and philanthropic organizations which touch these lives at any point, we may set some check to the contagion. There is already a natural check to it, if we can trust the general evidence of our records, as an examination of the cases of pauperism in the second generation shows a tendency to elimination by infertility and early death."

All these matters we maintain are so intimately associated with the general health of the community that they become medical as well as social problems.

Turning, however, to that part of the report which concerns itself chiefly with the strictly medical side of the work, we find a highly encouraging outlook for

the future. The visiting medical staff reports progress in every direction, which has been due in great measure to the hearty co-operation it has received from the trustees, superintendent and resident medical staff. With all the difficulties attending the care of the class of patients of which the hospital is largely composed, an excellent degree of discipline has been attained, and a distinctly hospital spirit introduced.

In the words of the report, "No one thing has conduced more to orderliness than the commitment to proper hospitals of noisy and troublesome insane patients. The policy has been to transfer those persons who, through their disordered mental state, have interfered with the welfare of non-insane patients, thereby relieving the hospital of patients for whom it is not intended and also assisting toward a proper classification of the dependent poor." It would seem to us altogether desirable that this policy be consistently carried out. The principle is undoubtedly sound, and it is the duty of the city to provide accommodation in all cases for the troublesome insane, in institutions where they will be neither a menace nor a disturbing element to patients who are not mentally affected.

It is also of interest to note the fact that since the introduction of adequate methods of infant feeding the deaths due to digestive disturbances have been reduced to one-quarter of what they were, a result perhaps partly due to the equipment of a sunny nursery. During the period immediately after the war with Spain one hundred and twelve soldiers were treated, with no deaths.

The visiting staff in concluding their report make the following statement: "In conclusion, we beg leave to state that, in our opinion, one of the most pressing medical needs of the city is a properly appointed hospital to which those suffering from incurable disease may be sent. This need the Long Island Hospital should supply more completely than is at present the case. To this end we hope that in time persons may be admitted to the hospital for temporary or permanent treatment, without the stigma which attaches to the name of pauper. Could this be accomplished, we feel sure that the range of usefulness of the hospital would be materially extended."

SCIENTIFIC STUDY OF PHYSICAL TRAINING.

IN our issues of August 31st and September 7th was published a paper by Dr. Eugene A. Darling, on "The Effects of Training. A Study of the Harvard University Crews." We desire to call attention not so much to the details of Dr. Darling's interesting investigation, for which we would refer our readers to the original paper, as to the significance of such studies in general with reference to the highly important matter of athletic training.

As in every other question which excites much public attention, there have been two fairly well-defined points of view regarding the effects on the participants of athletic contests requiring a high degree of skill and muscular effort. The enthusiast for sport has strenuously maintained that only good results to the individual and to the general cause of physical development. The more conservative, but often no less interested, believer in athletic sports has urged that the training incident to one of our great college contests is inconsistent with physiological laws and, on the whole, is harmful rather than helpful to the individual, and hence to the general cause of athletics. Both of these opinions have no doubt been sincerely held, and many theoretical arguments have from time to time been adduced in support of one or the other view. The point of interest, however, is that a matter capable of approximate demonstration has been so long neglected, and no really scientific study made of the men undergoing training, to determine the actual results of the contests upon their bodily processes and organs. It is clearly a matter about which it is useless to theorize when certain definite facts may readily be determined. When facts are exhausted, theories may be in place, but not before.

It is for this reason that Dr. Darling's investigation is of great significance. He has had the opportunity of studying a body of highly trained men both before and after a contest requiring a high degree of skill and muscular endurance and has tabulated his results. He has found that certain changes in the circulating apparatus and excretory organs are easily demonstrable by means of the methods of physical diagnosis now at the disposal of any well-educated physician. The positive results he has given us are of the greatest importance in themselves and as a basis for further investigation, and the way has thereby clearly been opened for a substitution of fact for theory. Williams and Arnold have also done valuable work in the same line in determining certain physical conditions resulting from long-distance running. The methods which these investigators have adopted need merely to be extended, as Dr. Darling admirably points out, until we have a science instead of a theory of physical training. There is here evidently a field for much good work. The metabolic processes must be studied; the excreta examined chemically, the manifestations on the part of the nervous system closely scrutinized; statistics extending over years must be compiled and compared, and when all this is done we may frame our theories. Unquestionably the greatest need of the present is to tabulate exactly the physiological effects of training and of violent athletic contests, in order that we may as soon as possible get at a criterion, which will bear scientific analysis. This is certainly possible, and such work as Dr. Darling has just published does much to hasten the day. That it has been so long in coming is undoubtedly a reproach to our methods of physical training hitherto in vogue, and should be a stimulus to renewed work along these lines in the future. We have no doubt that many obscure questions will thereby be settled.

MEDICAL NOTES.

THE YELLOW-FEVER SITUATION. — No new cases of the disease have developed at New Orleans. Cases at Mississippi City are reported as mild and doing well. At Key West up to a few days ago there had been 135 cases and 10 deaths. Several passengers on the steamer *Lampasas*, from Galveston and Key West to New York, have shown suspicious symptoms, and one has developed the disease. In Cuba during the month of August there were 55 cases and 20 deaths.

DEATH-RATES OF ABSTAINERS AND DRINKERS. — According to the *Medical Record*, of 4,234 deaths collected by the British Medical Association the ages of death in classes were registered, together with the cause, and the average of death for each class computed with the following result: Total abstainers lived on an average 51.22 years. The habitually temperate class lived on an average 62.13 years. Careless drinkers lived on an average 59.67 years. The free drinkers lived on an average 57.59 years, while habitual drunkards lived on an average 52.03 years.

HOSPITALS IN THE PHILIPPINES. — In view of the increased army now being sent to the Philippines, we learn from the *Medical News* that Surgeon-General Sternberg has issued orders for an increase of the medical department and hospital accommodations at Manila. As six months is required for building a large wooden hospital, it will be necessary to depend either upon tent hospitals or upon buildings already constructed which may be obtained for the purpose, so five hundred hospital tents have been ordered. Two hundred and fifty members of the hospital corps will be sent on the *Missouri* and twenty female nurses on the *Relief*. Four experienced surgeons of volunteers, with the rank of major, are now under orders for Manila in addition to the commissioned medical officers belonging to the new volunteer regiments.

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, September 13, 1899, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious disease: diphtheria 60, scarlet fever 14, measles 6, typhoid fever 38.

NEW YORK.

IMPROVED BUILDING LAWS. — The members of the Tenement House Commission which was appointed in 1894 to study the field of tenement house construction and report to the Legislature, and whose recommendations were later embodied in building laws, have expressed the unqualified opinion that the new building code of the City of New York, which has just been prepared by the Building Code Commission, will tend to improve the construction of tenement houses as well as of other buildings. The reduction in the thickness of walls and of floors, rendered possible by the improved methods of construction now in use, which the new code permits, is regarded as an advantage in tenement houses, and the section of the code applying to fire appliances is looked upon as especially advantageous for tenements.

CHARGES AGAINST THE SOCIETY FOR PREVENTION OF CRUELTY TO CHILDREN DISMISSED. — Albert Stickney, appointed referee by the Supreme Court to inquire into the charges of mismanagement preferred against the Society for the Prevention of Cruelty to Children, has filed a voluminous report in which he sustains in every instance the claims and defence put in by the Society, and praises its management in the highest terms.

A DINNER FOR NAVAL PHARMACISTS. — The Manhattan Pharmaceutical Association is making arrangements to give a banquet in honor of the pharmacist of the *Olympia* at the time of the Dewey celebration, to which the pharmacists of Admiral Sampson's escorting fleet are to be invited. The *Olympia's* pharmacist is said to be the youngest officer of his grade in the service. In June, 1898, a bill was enacted providing for the appointment of twenty-five pharmacists, with the rank of warrant officers. These appointments were made from among the senior apothecaries in the service, with the exception of the apothecary of the *Olympia*, who, for distinguished services, was promoted to this rank, although he had been in the service only about ten years.

DEATH OF SISTER CONSALVA. — Sister Consalva, who was for thirteen years the Mother Superior of the Sisters of St. Francis of the Poor in charge of St. Peter's Hospital, Brooklyn, died at the hospital on September 4th. When she became Mother Superior of the Sisters at St. Peter's that institution was located in a small frame building, and it was chiefly through her efforts that the fine structure now occupied by the hospital was built. She was a native of Germany, and sixty-seven years old.

Miscellany.

PUBLIC MONEY FOR PRIVATE CHARITIES IN NEW YORK.

ON September 7th Controller Coler presented in the Board of Estimate and Apportionment a resolution embodying the terms and conditions on which he thinks it advisable that any public moneys appropriated from the city's budget for the support of private charities should be dispersed. Accompanying it was an exhaustive report on the general subject of such appropriations, to which the controller has been devoting so much attention in the last few months. In it he gives expression to the belief that the best results will be obtained if the Board of Estimate will decide upon a policy which should first decide clearly the relations to be established between the city treasury and private charitable institutions, and then move toward that end by gradually conforming the appropriations in the budget to that ideal in such a manner that progress shall be made as rapidly as may be consistent with the desire to avoid crippling excellent charities which have

been led to depend for many years upon public assistance.

The city's appropriations for paupers in private institutions increased from $1,845,872 in 1894 to $3,131,589 in 1899, and in view of the additional responsibility placed upon the Board of Estimate by the Stranahan Act, the controller says, he made a thorough investigation of the existing conditions. All institutions receiving public moneys were requested to submit sworn statements as to their work and finances, and these, together with special reports from the State Board of Charities, the State Charities Aid Association, the Charity Organization Society and the New York Medical League, accompany his report. A considerable portion of the latter is devoted to medical charities, in which the present system finds its greatest abuses, and in commenting on this topic Mr. Coler says, in part:

"While sometimes overcrowded, it frequently happens that the city hospitals are not filled to the limit of their capacity, and it would seem as though the city should not deal with private hospitals except as subsidiary aids or adjuncts to the public institutions. It stands to reason that as long as there are vacant beds in the city hospitals, and the city is at the same time subsidizing private hospitals at a cost greater than the expense of caring for patients in its own institutions, a wrong is done to the taxpayers. If private hospitals are to receive public assistance at all, it would certainly seem that payments should be made only at some uniform rate approximately the same as the cost *per capita* of maintenance in the public institutions (not including the cost of general administration, which would be constant in any event)."

The appropriations for dispensaries for next year, he recommends, shall be limited to one-half the amount appropriated in 1899.

THE ETIOLOGY OF BERI-BERI.

THE *British Medical Journal* refers to an interesting contribution to the subject of beri-beri, in which Dr. Laurent gives an account of a sharp epidemic of this disease which attacked the Annamite soldiers forming part of the French troops of occupation of Chautabun (Siam). Acting on the view of Dr. Brémaud that fat plays an important part in the prevention of beri-beri, steps were taken to include this important article of diet in the rations, and in forty-eight hours the epidemic was arrested. That the absence of fat in the dietary is not the sole factor in the production of the disease was proved by the fact that one of the worst cases occurred in a Frenchman, but he was the only European attacked, and rapidly recovered on removal from Chautabun. This case would point to an infectious factor. On his return to Saïgon, Dr. Laurent had an opportunity on the voyage of visiting the island convict settlement of Poulo-Condore, where he found beri-beri very prevalent — in fact, there had been 360 deaths from it in the year, and there were no fewer than 160 cases under treatment. His experience of the influence of fat on the course of the Chautabun epidemic led him to recommend its trial, with beneficial results. Commenting on the foregoing, Dr. Brémaud refers to his experience of the Poulo-Condore Settlement in 1877–78, when the cutting off of fat in the dietary of the convicts was followed by a severe outbreak of beri-beri with many deaths. The epidemic immediately ceased when the original fat-containing diet was resumed. Dr. Brémaud also observed an outbreak on board the English vessel *Ilione* in 1879, whilst in charge of a consignment of coolies shipped from Pondicherry to Martinique. During the voyage, which lasted four months, Mohammedans only were affected by the disease. On religious grounds they systematically abstained from fat (pork). The other coolies who partook of the pork escaped. These facts certainly point to the importance of fat, and there should be no difficulty in putting the views of the French observers to the test. In this connection it would be interesting to know what part fat formed of the dietary of the Richmond Asylum, Dublin, before the appearance of beri-beri there. There can be no doubt that suet, dripping, fat pork, the fat of milk, and so forth, are most valuable articles of diet, and their exclusion from the dietary a fruitful factor in the development of rickets, tuberculosis, and possibly of leprosy also.

HOSPITALS AND MATRIMONY.

THE *Medical Press and Circular* very sensibly comments as follows on the relation between nurses and medical officers in institutions where they are naturally much thrown together.

"A discussion which ought by rights to have been relegated to the silly season has been carried on in one or more of the New York newspapers concerning the matrimonial propensities of the nurses employed in the large general hospitals of the metropolis, though it is not pretended that the practices complained of are by any means limited to this *milieu*. The allegations in the main do not impugn the morality of the nursing fraternity, or shall we say sisterhood, but it is asserted that nurses and doctors 'flirt and carry on,' and that many nurses regard the hospital as a field for the matrimonial campaign. There is doubtless a certain amount of truth in this, for most of us can call to mind numerous instances of marriage between medical residents and nurses and even between nurses and their patients. Whenever a young man of prepossessing appearance is brought into daily and even hourly contact with a comely young woman, shown to advantage in a neat attire, who is not on principle averse from matrimony, there is always the possibility, *Dieu merci*, of a matrimonial sequel, and although a hospital ward is not an ideal *milieu* for Cupid's ravages, the very community of purpose and emotions paves the way to tenderer feelings. The rules at most institutions err, if anything, on the side of severity in the direction of repressing and reproving any intimacy between medical officer and nurse, but though they may hinder flirting pure and simple, neither they nor any rules that female ingenuity, as represented by the matron, may devise can be relied upon to stamp out this very human instinct — nor should we approve them if they did."

THERAPEUTIC NOTES.

TREATMENT OF MASTITIS BY INTRAGLANDULAR INJECTIONS OF CARBOLIZED WATER. — Dr. W. Rubeska,[1] professor of obstetrics in the School of Mid-

[1] Bulletin Général de Therap., July 30, 149.

wifery at Prague, adopts the following treatment for mastitis in nursing women. As soon as an inflammatory infiltration of the gland is detected the nipple is thoroughly disinfected, and compresses saturated in a 0.5-per-cent. solution of sublimate are applied to it for two hours. Then the excess of milk in the breast is drawn off by aspiration and an ice-cap applied over the breast. When the mastitis begins with a chill followed by fever and severe pains, an injection is at once made into the depth of the parenchyma of the infiltrated organ of two or three cubic centimetres of a three-per-cent. carbolized water. If the beginning of the affection is less pronounced, then the injections may be made on the next day, in case the fever and the pains do not subside. Out of 16 cases in which Rubeska employed this method of treatment, the formation of an abscess was avoided in 14; the temperature became normal on the same day when the injections were made, and by the following day the inflammatory infiltration began to disappear rapidly. In some cases it became necessary to repeat the injection a second or even a third time, on account of the formation of fresh inflammatory points in the same breast or in the opposite one.

The Treatment of Pleurisy by the Local Application of Guaiacol.— Prosoroffsky [2] treated 11 cases of pleuritic effusion by the local application of guaiacol over the skin of the affected side; he finds that the absorption of the effused fluid takes place more rapidly than when any other method is employed, without causing any inconvenience to the patient. The applications are generally repeated six or seven times, after which a fall in the temperature is noted from one to five degrees F., although it rises again in a few hours. The action of guaiacol is explained thus: First, an effect is produced on the peripheral nerves which influences appreciably the vasomotor centres, and secondly, the guaiacol being absorbed by the tissues destroys the noxious agencies elaborated by the pathological process in pleurisy.

Cardiac Medication in the Treatment of Epilepsy. — Bechterew [3] recommends the addition of adonis vernalis to the potassium bromide in the treatment of epilepsy, and refers to a case in which this mixture was employed with success in an adult who was to be subjected to a trephining. In certain cases, which he does not specify, he finds it more advantageous to substitute the adonis by infusion of digitalis, thus, infusion of digitalis 0.5 to 0.75 in 180 of water; potassium or sodium bromide, six to eight parts; codeine, 0.15 to 0.20; of this five to eight teaspoonfuls during the day. No cumulative effects have ever been observed. This therapeutic indication may be explained by the cardiac aura, by the acceleration of the pulse during an attack of epilepsy, by the diuretic effects of the drug, which brings about a carrying away, as it were, of the attack-producing toxin, and by the vasomotor effect (of the vaso-constricting property of adonis vernalis), which counteracts the congestion of the vessels of the brain, as observed in two patients of the author during an attack.[4]

Dermatol in Diarrhea of Children. — Dr. Poix [5] administers dermatol in doses of one gramme per day to children of six months and under, or two grammes and more to older ones. It is administered in any mucilaginous vehicle, a teaspoonful every hour. The results are highly satisfactory.

The Therapeutic Application of Common Table Salt Injections.— Dr. M. Eltz [6] finds that the colon absorbs more readily quantities of normal salt solution than ordinary water. Even in cases in which irrigation is followed by evacuation of the bowels, half or even more of the injected fluid remained in the organism. The solution was employed by the author in many cases of gastric atony, in a few cases of chronic nephritis and once in whooping-cough. In atony of the stomach the author succeeded, by the aid of the injection, in quenching the thirst without burdening the stomach. In nephritis large injections of the normal salt solution one half-hour before the production of sweating in the ordinary course of treatment enhanced greatly the effect of the sudorific. In the case of whooping-cough in a child that was unable during several days to retain a single drop of water, and suffered for two days with complete anuria, a few irrigations with the normal salt solution entirely removed these troublesome symptoms. Among other indications for the employment of this solution he also considers sudden hemorrhages and vomiting of pregnancy. Finally they are also used in cases where rectal alimentation is indicated.

Ichthyol in Anal Fissures.— Conitzer [7] used the drug in eight cases in the following manner: After anesthetizing the parts with cocaine, pure ichthyol is rubbed in on a glass rod, at first daily, and then every other day without cocaine. The stool must be watery.

Bronchitis:

℞ Terpinol, Sodi benzoatis, Sant. albi āā . . . . . gr. ii
Sig. Take six to twelve per day. q. s. et ft. pil. No. 1.

Correspondence.

A CORRECTION.

New York, September 10, 1899.

Mr. Editor: — In your issue of September 7th, p. 243, there is the following sentence, meant to be an extract from a paper read by me before the American Climatological Association (*Transactions*, Vol. XV, 1889): "When the child's heart is developing the cavities enlarge, but the wall of the heart does not always grow thicker."

I take it for granted that a great many of your subscribers read your columns with the same attention that I do and are influenced by them. That is why I refer to the grave error contained in the above statement. On p. 244 of the *Transactions* I say: "The heart of the young is comparatively large, heavy and healthy. Its weight in the newly-born is 0.89 per cent. of the body weight; in the adult 0.52 per cent. In the newly-born the cavity is small, 23 c.c. . . . the muscle is massive, equally thick on the right and left sides. . . . During the first five years there is an increase of the heart in bulk and weight, but none in circumference. . . . The cavities dilate rapidly only after the fifth year."

Very respectfully,
A. Jacobi, M.D.

Deaths reported 2,464; under five years of age 1,065; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 547, consumption 260, acute lung diseases 159, diarrheal diseases 364, diphtheria and croup 84, typhoid fever 48, whooping-cough 30, cerebro-spinal meningitis 18, erysipelas 15, scarlet fever 10, measles 6, malarial fever and small-pox 1 each.

From whooping-cough New York 17, Philadelphia 6, Boston 4, Baltimore, Cambridge and Waltham 1 each. From cerebro-spinal meningitis New York 14, Boston 3, New Bedford 1. From erysipelas New York 12, Pittsburg 2, Baltimore 1. From scarlet fever New York 4, Pittsburg 2, Philadelphia, Boston, Providence and Salem 1 each. From measles New York 6. From small-pox Boston 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending August 26th, the death-rate was 26 8. Deaths reported 5,868; acute diseases of the respiratory organs (London) 170, diarrhœa 1,587, measles 105, diphtheria 72, whooping-cough 71, fever 58, scarlet fever 25, small-pox (Hull) 1.

The death-rates ranged from 20.8 in Croydon to 38.0 in Salford; Birmingham 30.7, Bradford 24.1, Cardiff 24.1, Gateshead 27.9, Hull 26.3, Leeds 23.2, Liverpool 36 7, London 24.1, Manchester 33.7, Nottingham 30.1, Portsmouth 32.0, Sheffield 29.5, Swansea 22.1, West Ham 25.7.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 9, 1899.

E. H. MARSTELLER, surgeon, ordered to duty in connection with recruiting rendezvous, Buffalo, N. Y., to report at the New York Navy Yard, September 4th.

B. R. WARD, passed assistant surgeon, J. F. CHAFFEE, assistant surgeon, are detached from the "Boston" when put out of commission and ordered home to wait orders.

J. C. DECKER, surgeon, detached from the "Monadnock" and ordered to the "Monocacy," at own expense.

J. STOUGHTON, passed assistant surgeon, detached from the "Monocacy" and ordered to the "Monadnock," at own expense.

SOCIETY NOTICE.

TRI-STATE MEDICAL SOCIETY OF ALABAMA, GEORGIA AND TENNESSEE. — The eleventh annual meeting of the Society will be held in Chattanooga, Tuesday, Wednesday and Thursday, October 24, 25 and 26, 1899.

Those desiring to read papers should send titles to Frank Trester Smith, M.D., Secretary, Chattanooga.

BOOKS AND PAMPHLETS RECEIVED.

The Disinfection of the Alimentary Canal. By A. Jacobi, M.D., LL.D., New York.

Annual Announcement and Catalogue of the Baltimore Medical College, Session of 1899-1900.

Advice to Gonorrheal Patients. By Ferd. C. Valentine, M.D., of New York City. Reprint. 1899.

CORRECTION IN LATERAL CURVATURE.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D., BOSTON.

As lateral curvature is in the main a vice of position and attitude, the treatment is directed chiefly towards the correction of faulty position and attitude. This treatment necessarily depends upon the pathological conditions, which vary at the different stages of development and severity of the affection, and these variations may be described as follow:

(1) Faulty attitudes with absolute flexibility of the spine, and without structural changes of ligaments, cartilage or bone.

(2) A curved position of the spine with flexibility, except to a limited degree in certain portions where the normal flexibility is checked by slight structural alterations of muscles, ligaments, or cartilage.

(3) Curves with limited flexibility of the spine, and with structural changes of the ligaments and cartilages.

(4) Stiffness of the spine, the curve being fixed by structural changes in the ligaments, cartilages and bone.

When individuals have attained their growth, and there is evidence of marked bony change, treatment must necessarily be palliative, but in individuals that have not reached full growth, even if structural changes are present, treatment can be expected to be of service in proportion to the amount of resistance to correction from the shape and structure of the bones.

The treatment in the first and second class would necessarily be largely gymnastic. In the second class the treatment should consist of gymnastics, supplemented by the use of measures for the increase of the flexibility of the spine, that is, the stretching of shortened contracted ligaments. These methods of treatment have already been fully discussed in previous papers on the subject. In the third class of cases, where resistance and flexibility of the spine exist, owing to firm structural changes, treatment by gymnastics and flexibility exercises will not be sufficient, and for these cases mechanical measures have always been attempted. They have, however, never been thoroughly successful as corrective measures, largely owing to the mechanical difficulty that is encountered. The important problem, therefore, before the orthopedic surgeon, is the selection of the best possible means of exerting pressure directly upon the projecting positions of the trunk.

The large number of variety of corsets that have been devised show the need of some method of treatment of the sort, but the great number of appliances used also indicates the lack of serviceableness and defects of most of them. It was supposed that the treatment by plaster jackets suggested by Sayre would be corrective, but the subsequent experience has shown that although this method is of value in caries of the spine, its value is considerably less in lateral than in anteroposterior curves from caries. The reason of this is manifest from the fact that suspension as applied by Dr. Sayre does not sufficiently correct the twist of the spine seen in lateral curvature.

It may frankly be admitted that the difficulties presented by extreme curves may be insurmountable or may be only partially overcome. If more pressure is required and for a longer time than can be borne by the patient for the correction of the curves of the bone, or for adaptive changes in the muscles and ligaments, manifestly no correction can be made.

Conversely, however, experience has taught that if sufficient pressure is applied properly, faulty shapes of bone in growing children can be corrected in various portions of the skeleton, jaw and long bones, and we need this pressure so severe as to be unendurable, provided it be constantly or continuously applied. Bone may be expected to grow straight, if it is prevented from growing crookedly. The softer the bone and the younger the child the more easily is the change produced.

Removable appliances are necessarily less efficient than fixed ones, owing to the difficulty of thorough adjustment after removal, and of fixed appliances, plaster-

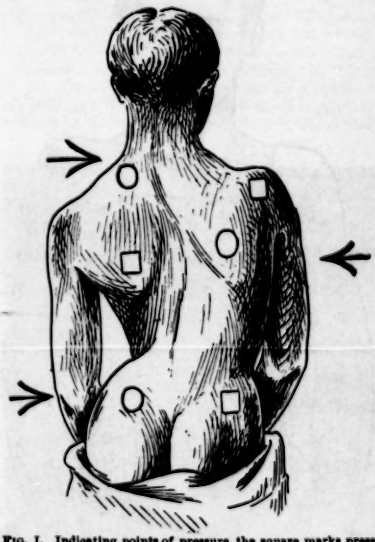

FIG. I. Indicating points of pressure, the square marks pressure in front and the round marks pressure behind.

of-Paris corsets are more easily worn, and more readily adjusted than anything yet devised. It is, however, necessary that they should be applied in such a way as to exert and maintain the desired pressure, as long as it is considered necessary to maintain corrective pressure.

A plaster jacket as ordinarily applied in lateral curvature often slips on wearing and presses upon the concavity, injuring as much as it corrects, even if it corrects at all. It is manifest that the jacket should be applied with the patient corrected as far as possible, and with the patient kept in the corrected position, until the plaster-of-Paris is sufficiently hard to maintain the correcting pressure, and that this correcting pressure should be as great as can be borne without distress and applied in the best possible directions.

It is not the purpose of this paper to relate the details of the experience gained upon the subject. It

will be sufficient to mention that the most feasible way of straightening the spine has been found to be by the removal of the superimposed weight by the recumbent position, rather than by vertical suspension, as the latter is less easily borne by the patient. It is also true that the use of an anesthetic in the correction for lateral curves has manifest disadvantages, and cannot be as frequently applied as is usually necessary for increasing correction in lateral curves.

In cases such as are suited to correction by this method, if the patient is placed upon the back, with or without head and foot traction, the middle line of the trunk can be made straight. Furthermore, if the patient lies with the weight of the trunk supported only upon certain points, where upward pressure is applied, the sag of the unsupported portions of the trunk will serve to aid in the correction of the twist of the trunk. This correction of the twist may be aided by pressing upon the prominent portion of the distorted chest and thorax, using for this purpose hand pressure downward, during the application of the plaster, upon the front of the patient, while the supporting points on which the patient lies exert an upward pressure.

FIG. II. Jacket applied.

In the ordinary curves of lateral curvature the portions requiring correcting pressure in the back are, (1) on the projection of the shoulder, or adjacent part of the thorax, below the scapula on one side, and (2) on the opposite side above the scapula or at the base of the neck, and (3) in the lower portion of the trunk in the lumbar region on the side opposite to the prominent shoulder.

In front, correcting pressure is to be exerted (1) on the thorax at its prominent part on one side; (2), on the head of the humerus or acromial end of the clavicle, and (3) projecting pelvic anterior-superior spine on the other. (Fig. I.)

Pressure in this way can be applied without discomfort to the patient, if supporting rods bearing small, removable plates of aluminum (over which felt is laid) are placed under the recumbent patient's back at the required points, the head, pelvis and thighs being supported by cushions on a table, or by straps stretched across a gas-pipe frame. The plaster bandages are applied as usual. Downward pressure can be made upon the thorax and shoulder while the plaster is hardening, and when the corset is firm the patient sits up, leaving the adequately padded aluminum plates incorporated in the plaster bandage, and exerting constant pressure. It is desirable that the plaster pass over the shoulder, close to the neck

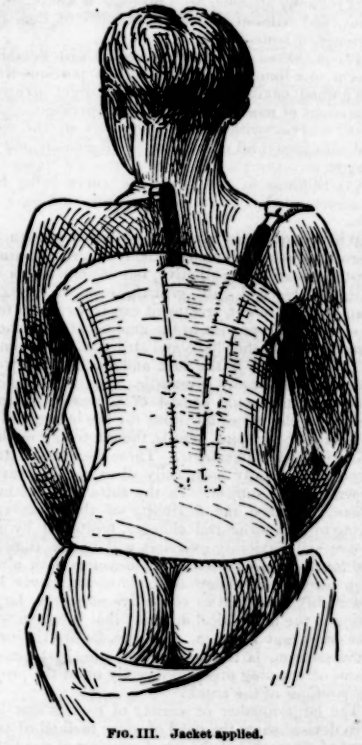

FIG. III. Jacket applied.

on the side of the projecting neck (that is, on the side opposite to the projecting shoulder), or that a strap attached to a steel be adjusted exerting pressure at this point. If this is not done, the corset will tip when the patient is erect, and the points of correcting pressure will be lost, the upper edge of the back of the corset pressing into the concavity of the curvature in the back, and the full benefit of the correcting lost. The acromial end of the projecting shoulder is to be kept back by a padded strap. (Figs. II and III.)

A correcting force should manifestly be applied not beyond the point of easy endurance and the jackets should be frequently changed. The treatment should be continued as long as it is possible to obtain correction, after which a removable corset and gymnastic treatment is to be employed. (Fig. IV.)

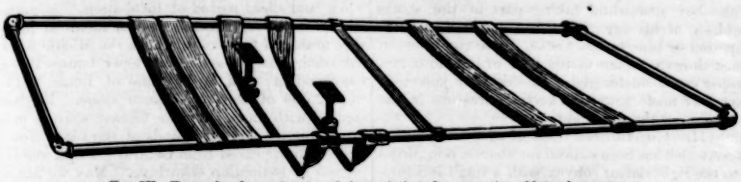

FIG. IV. Frame for the application of plaster jackets for correction of lateral curvature.

A few cases will serve as an illustration of this method.

CASE I. Girl, sixteen years of age, with low curve, rotation, spine moderately flexible, has been weak since a period of rapid growth, and unable to carry out systematically any definite exercise. The attempt was made to wear a removable corset, but owing to the child's condition, this was not successful, and the curve of the back had begun to increase. In view of this the plaster jacket was applied as a matter of trial, although it was felt at the time that possibly it could not be worn, but after two days it was found to be entirely comfortable and the patient much preferred it to any other form of treatment.

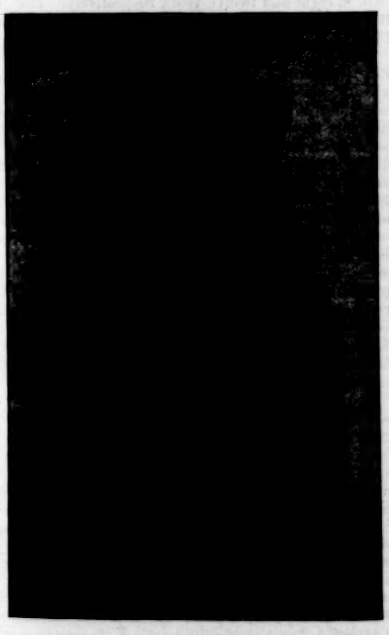

FIG. V. Case III before treatment.

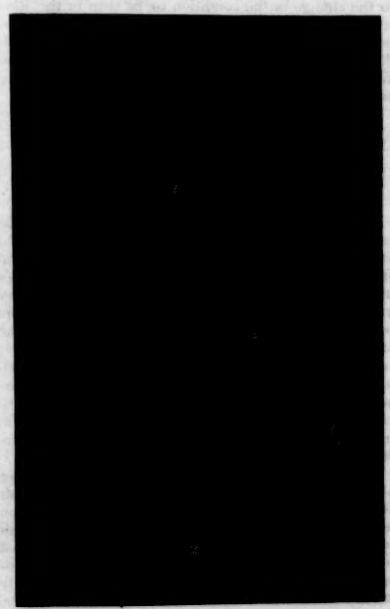

FIG. VI. Case III after two months' treatment.

CASE II. Boy, thirteen years of age, has worn removable jacket and attempted gymnastic exercises for over a year, but attention to this has not been satisfac-

tory, owing to the difficulty in making the boy carry out systematic treatment. There is a decided curve to the left in the lumbar region, with rotation, and slight curve to the right of dorsal region above. Suspension or recumbency does not obliterate the deformity.

The jacket was applied and worn with perfect comfort, the boy meanwhile taking part in the sports of children of his age. The first jacket was worn for a period of nine or ten weeks. The condition of the back shows complete obliteration of lumbar curve, the upper curve unchanged. In this first jacket no attempt was made towards exerting pressure in the dorsal region of the upper curve.

CASE III. Girl, thirteen years of age, with a resistant curve, which has been noticed for about a year, usual type, to the right dorsal convex with a small left lumbar convex curve. The curve did not disappear on suspension or recumbency, and there was a permanent rotation of ten degrees. This case presented an unusual degree of inflexibility in a patient of her age. Even by employment of considerable manual force in the recumbent position the curve could not be corrected.

The accompanying photograph shows the result in this case after the removal of the second jacket applied by the method described in this paper. In addition to the change in the condition to be seen in the illustration, an improvement in flexibility was noticed, so much so that with the child recumbent not only did the lateral deviation disappear, but there was improvement in the rotation, which by means of slight manual pressure was much more diminished.

THE STRUGGLE AGAINST TUBERCULOSIS.[1]

BY EDWARD O. OTIS, M.D., BOSTON.

No more striking and dramatic illustration of the use and neglect of measures for the prevention of disease has recently occurred than that of General Shafter's army at Santiago, and Colonel Huntington's marines at Guantanamo. The condition of the former army on its return to this country is too familiar to you to require further comment. One could not observe the latter body of men without being impressed with their sturdy, robust appearance, indicating the best of physical condition; and yet both had been under the same local and climatic conditions. The difference in results was principally due to the recognition and use in the one case and the disregard in the other of preventive measures of disease.

As evident as the advantages of prevention are over later attempts at cure, it is one of the most difficult and disheartening struggles to impress this fact upon the general public, and this is particularly true with regard to pulmonary tuberculosis. Long accustomed to its presence and entertaining the old ideas of inheritance and incurability, one listlessly and hopelessly bowed to it as to the inevitable. Of late, however, there has been a change of attitude and an awakening with regard to it all over the civilized world, growing steadily stronger and leading to practical measures for its prevention. The discovery of the tubercle bacillus, establishing the unity of the disease, has given a definite and exact basis upon which to work, and excited a hopefulness as to its restriction, if not to its ultimate extinction.

We may learn a lesson and gain encouragement in our struggle against this disease from the history of leprosy in Central Europe. Leprosy is a disease which bears a very close resemblance to tuberculosis. It has a "long and silent period of incubation," is contagious, and its micro organism is almost identical in appearance to that of tuberculosis. In the Middle Ages there were computed to be 19,000[2] leper houses throughout Christendom; and in the time of Louis VIII there were 2,000 of them in France alone. England was studded with them, and the disease existed in almost every country and the islands of the sea. Now it has entirely disappeared from Central Europe, and is in the process of extinction elsewhere. May we not reasonably hope that in like manner tuberculosis, under measures of prevention which experience has demonstrated possible of execution and effective, may suffer the same fate as this its allied disease? Already evidence exists which points to this result.

The mortality from consumption in England and Wales was over 38 per 10,000 in 1838; 24 in 1870, and nearly 14 in 1895. In Philadelphia and New York the mortality has been reduced 20 and 30 per cent. in eight and twelve years respectively. Here in Boston it has been reduced from 18.25 per cent. in 1871 to 11.55 per cent. in 1897.

As with other communicable diseases, we must be able to locate the tuberculous cases and control them when necessary; this seems to me essential and fundamental to any efficient prevention. Whether we obtain this knowledge by compulsory notification or depend upon the voluntary reports of the physician is still a debatable question. My own opinion is that sooner or later consumption will be included among the infectious diseases, and even the public may demand it as the result of our own teachings. At all events, we must have knowledge of the cases and their locality. Of course this is the most important among the poor in the tenement-house districts, where little attention to prevention is likely to obtain. The well-to-do and the more intelligent portions of the community can generally be depended upon now to observe the proper precautions as to the disposal of the sputum; this they have learned from the anti-spitting propagandism.

The importance of disinfection or renovation after a case of phthisis is, however, in my experience not generally appreciated. No tenement, apartment or room should be again occupied or let until satisfactory evidence of thorough disinfection or renovation has been furnished. A case narrated to me by a physician of this city will illustrate the importance of this. The daughter of the landlady of a well-to-do boarding house dies of consumption. Some time afterwards a young woman from the West takes up her residence in the boarding house and occupies the daughter's room. In the course of time she exhibits evidences of tuberculosis, and her physician, suspecting the source of infection, has her removed. Such experiences are probably familiar to many of you. To my knowledge the disinfection of premises which have been occupied by consumptive patients and vacated either by death or removal, before they can be occupied, is compulsory only in New York City, Italy and Spain.

[1] Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, March 15, 1899.

[2] Ransome: Causes and Prevention of Phthisis. Wood's Medical and Surgical Monographs, April 1891, p. 190.

The great struggle, however, is with the poor and ignorant consumptives who probably constitute a large majority of those suffering from the disease. They cannot be depended upon to safely dispose of the sputum either at home or abroad when they are still able to be about or attend to their occupation. In the latter stages of the disease they are often too weak to do so even with the best intention. The only resource then is isolation in especial consumptive hospitals or sanatoria, a step which is being agitated and indeed in the process of accomplishment, as I shall later show, in Europe and to a very limited extent in this country.

As in the Middle Ages the leper asylums existed, so in this age must we have the consumptive hospitals for the poor if the disease is ever to be exterminated. Not one but several such institutions would be required in or near every large city, which should afford free accommodation for consumptives in every stage. Those in the earlier stages and those exhibiting improvement under treatment could later be transferred to a sanatorium proper for the open-air treatment, conducted by the State, as at Rutland, or supported by voluntary contributions. Thus could the public be protected and the consumptive afforded an opportunity for recovery if possible, or receive comfortable care while he lived, which multitudes of them do not now receive. "I can conceive few objects," says Ransome, "better calculated to excite the compassion of all humane people than the condition of many of these poor sufferers who are shut out from the benefits of general hospitals." "In the place of the half-dozen such institutions," continues this same authority, "outside the Metropolis (London), there ought to be hundreds of them scattered about the country, in suitable localities and attached to all the chief centres of the population." But would not the expense of establishing and supporting such institutions preclude the undertaking either by the municipality, State, or through private beneficence?

"The poor laborer," says Dr. Cheever in his recent address at the opening of the new surgical amphitheatre at the City Hospital, "knocked down and crushed, receives here perfect nursing, asepsis, which means life and cure, good surgery, kindness and abundant food. He commands instantly an intelligent care and skill which the well-to-do have to wait and seek for, and even the rich sometimes do not attain."

If the city considers it a wise expenditure as well as a duty to offer such accommodations and treatment to the "knocked-down and crushed" poor laborer who is not a source of infection to any one else, would it not be at least an equally wise expenditure and duty to afford a refuge and treatment to the poor consumptive laborer, equally worthy, who may be a source of infection to those about him and the public, considering further the fact that the "knocked-down and crushed" laborers and all others who died a violent death in this city last year, for example, numbered 616, while those who died of consumption numbered 1,241? Morever, the city and State already are obliged to care for many of these poor sufferers in their almshouses and other institutions. To how much better purpose could the same amount be expended in especial institutions. Further, the number of consumptives by this means would be yearly reduced, which would mean a yearly saving of lives whose labor has a money value to the community.

As tuberculosis is caused by the ingestion of bacilli as well as by inhalation — and some authorities regard it as quite as frequent a cause — a rigid cattle inspection is an essential measure of prevention and especially of milch cows, for there does not appear to be much doubt that the largest part of ingestion tuberculosis is from tuberculous milk. The evidence of the danger from this source is abundant. In the recent investigation of the milk supply of Cambridge, England, more than half the dairies were found to be furnishing tuberculous milk, and it is not likely that this is a very exceptional state of things. I can see but one sure way of providing safe milk, and that is to require all milk-dealers to furnish satisfactory evidence that the cows from which their milk comes have been tested at stated intervals for tuberculosis and found free of the disease. Some cities already require this, as Syracuse and Minneapolis. The ordinance in the latter city is so comprehensive and thorough that it can profitably be quoted.

MINNEAPOLIS ORDINANCE FOR MILK INSPECTION.

"It shall be the duty of the Commission of Health to cause to be made by the veterinarian of the Department of Health, or under his direction and supervision, an examination of each and every animal producing milk for sale or consumption within said city and belonging to or controlled by said applicant, or the person from whom said applicant obtains milk, for the purpose of detecting the presence or absence of tuberculosis or any other contagious or infectious disease, and the said veterinarian of the Department of Health, in making such inspection and examination, is hereby authorized to use what is commonly known as the tuberculin test as a diagnostic agent for the detection of tuberculosis in such animals. After such examination and inspection of the dairies and dairy-herds as herein before provided, the Department of Health shall tag each and every animal so examined, which tag shall be of such a character as to afford a permanent record of such examination and the result of the same, as regards the presence or absence of any infectious or contagious disease."

In Massachusetts the appropriation for cattle inspection was refused by the Legislature last year, and it is again before that body this year. There are no State requirements as to the inspection of dairies or cows furnishing milk for the market. Some dealers on their own account have their herds tested, as, for example, the Deerfoot Farm. Sooner or later we shall realize the truth of the warning recently uttered,[3] "that economy in the regulation of tuberculosis is fearfully expensive economy, expensive in actual money, and above all, expensive in the lives and health of citizens."

A brief glance at the crusade against consumption in Europe may afford us encouragement. In nearly, if not quite, every country there is a general and active propagandism of prevention expressing itself in societies composed both of physicians and laymen, with the objects of raising money for the erection of sanatoria for the poor, and of issuing instructions to the people regarding the methods of avoiding the disease or communicating it to others. Most, if not all, of the governments have strict cattle inspection laws. In England recently the Prince of Wales presided over the Marlborough House meeting to establish a national society for the prevention of tuberculosis with the fol-

[3] Medical Record, Feb. 11, 1899, p. 176.

lowing objects: (*a*) To educate the public as to the means of preventing the spread of consumption from those already suffering from the disease; (*b*) to extinguish tuberculosis in cattle; (*c*) to promote the erection of sanatoria for the open-air treatment of tuberculous disease."

The secular press has also taken the matter up, and all the newspapers have frequent articles upon tuberculosis. The municipal councils of many cities are considering the question of establishing sanatoria. The Liverpool Hospital for Consumption has recently received a gift of $75,000 to extend its work.

For many years especial hospitals have existed in London and elsewhere in England for the isolation and treatment of the consumptive poor, in all sufficient to accommodate 4,900 persons. Of late the open-air treatment at home and in small hospitals is being advocated in England and tried with enthusiasm. In Germany almost every city of importance has its society for the erection of sanatoria and the general objects of prevention, Berlin, Cologne, Nuremburg, Worms, Munich, Würzburg, Hanover, Bremen, Frankfort, Breslau and others. In all Germany there are already in existence from twenty to thirty sanatoria for poor consumptives capable of accomodating 10,000 patients a year. An international congress on tuberculosis is to be held in Berlin in May of this year. In Denmark $100,000 has been collected for sanatorium purposes, and a law has been proposed in Parliament regarding free disinfection. Since 1893 a law for the suppression of tuberculosis in cattle has been in force in this country, with an annual appropriation of $14,000. In Russia the Emperor has donated $300,000 and a large tract of land upon which to erect a sanatorium in memory of the late Empress Marie Alexandrowna, who was a victim to phthisis. In Sweden the King, upon the occasion of the twenty-fifth anniversary of his coronation, donated $600,000, which had been presented to him by his people for some enterprise of public utility, for the erection of several sanatoria for poor consumptives. In Holland the young Queen, who was recently crowned, presented on this occasion $80,000 and a magnificent site for a sanatorium consecrated to the tuberculous poor. In Austria, under the able direction of Prof. Schrotter, a sanatorium has been erected at Alland, not far from Vienna, offering accommodations for more than 100 consumptives; those who are able do light work about the grounds. In France the profession has been exceedingly active in the struggle, as their admirable congress for the study of tuberculosis would indicate. There are also sanatoria at Angicourt, Armesson and Villiers-sur-Marne, with others projected. Belgium is likewise active both through the government and various societies throughout the kingdom instructing the public as to the dangers of tuberculosis and its prevention, and advocating the erection of sanatoria for the poor. Several institutions already exist on the seacoast for tuberculous children. Even in Greece and Turkey government disinfection is said to be carried out with marked benefit.

So it would seem that in a decade or two Europe would be dotted with consumptive hospitals and sanatoria, just as in the Middle Ages leper-houses existed everywhere, and as a result consumption would gradually decrease until, as with leprosy, it eventually became well-nigh exterminated.

In this country, in 1894, the following items were collected by Dr. Knopf,[4] of New York: Fourteen states have bovine laws and regulations and issue circulars regarding tuberculosis in man; two have bovine laws, but do nothing regarding tuberculosis in man; one has bovine laws, but no funds to enforce them; two have laws prohibiting the sale of tuberculous milk, but do nothing concerning the tuberculosis in the cows; eight have no bovine laws, but issue circulars concerning tuberculosis in man; seven have no boards of health, and from five no answers were received.

Before the Legislature of New York there is a bill pending for an appropriation for a sanatorium in the Adirondacks. The Board of Estimates and Apportionment in New York City has appropriated $60,000 for the purpose of isolating poor consumptives, and the Seton Hospital has been selected for this purpose. Compulsory notification also exists in that city and disinfection is required. In this State there is the Rutland Consumptive Hospital erected and supported by the State, for the reception of incipient cases who can pay $3.50 a week.

In this city (Boston) the estimated population in 1898 was 541,827, and the total mortality for that year 10,886, of which 1,241 were from pulmonary tuberculosis, 114 per 1,000 deaths, 79 more than all the deaths from measles, scarlatina, diphtheria, croup, whooping-cough, typhoid fever, cerebro-spinal meningitis, cancer and appendicitis combined. Of this number probably two-thirds, or 827, were of the poor classes. Leyden gives the ratio between the annual deaths and the total number of tuberculous persons as one to seven, which would give 9,928, or one out of every 54 inhabitants. The greatest mortality from consumption is between the ages of fifteen and sixty; that is, during the period of the greatest productive power of the individual. Estimating the value of a human life at $1,000, based upon what the individual has cost his family, the community, or State for his living, development and education, this community suffered a loss last year through pulmonary tuberculosis of $1,241,000. Further, as the consumptive is incapacitated from work a considerable time before he dies, his productive power is lost to that extent. Taking Gherard's[5] average of three months at $1.00 a day, there is a further loss of $111,690; a total of $1,352,690 for 1898.

If, now, by isolation and treatment in especial institutions the present mortality could be reduced one-half in a comparatively short time, as seems probable from the reduction which has already taken place in England and elsewhere, there would be a saving of $676,345 a year. Indeed, I believe that the expense of establishing especial institutions for this disease would be more than compensated for by this preservation of lives with years of service before them, and the added saving of the expense now incurred by the city and State in the care of the incapacitated consumptive.

At present there is no State appropriation for cattle inspection. Since December 22, 1898, the Board of Health requires that "the conditions under which every cow is kept whose milk is brought into the city of Boston shall be made known to the inspector of milk in such detail as the Board of Health may require," and, further, that "No milk shall be

[4] Journal of the American Medical Association, October 30, 1897.
[5] A Report of the Board of Health of the City of New York upon Pulmonary Tuberculosis, 1897.

sold, offered for sale or distributed in the city of Boston unless the cows from which it has derived have, within a year, been examined by a competent authority, and shown to be free from diseases dangerous to the public health; but this shall not be construed as forbidding the sale or use of milk from cows not tested with tuberculin." As, according to the conclusion of Ernst's very thorough investigations, "the possibility of milk from tuberculous udders containing the infectious element is undeniable," and "it is also equally undeniable that milk from diseased cows with no appreciable disease of the udder may, and not infrequently does, contain the bacillus of the disease"; and that, as has been demonstrated by the Cambridge investigation above referred to, a specimen of milk may be negative in its reaction one day, and a few days later show infection, and as the only possible and sure means in many cases of determining the existence of tuberculosis is the tuberculin test, which, as Nocard says, is exact and marvellously precise in its diagnostic indications, the only sure and safe means of eliminating tuberculosis from the milk would seem to be the tuberculin test, why then the last clause in the above regulations?

From the above considerations the Minneapolis ordinance, in the writer's opinion, ensures a greater security.

There is no certain means by required notification or otherwise of obtaining the knowledge of all the cases of consumption existing in this city or of locating them, and hence no complete supervision or control of them. There are no compulsory requirements of disinfection or renovation of premises occupied by a consumptive, or in which he has died, before occupancy is permitted to others. Disinfection, however, is done by the Board of Health if asked for. There are no means of isolating the poor consumptive, except the most limited in a few institutions; no general hospital cares to or ought to receive them. The homeless and friendless advanced cases and those too feeble to work must lead a miserable existence in their wretched tenements or go to the almshouse. The city has made superb provision for the poor sick with other contagious diseases, and for the poor "knocked-down and crushed laborer," but makes no adequate and proper provision for the poor consumptive, of whom at least 800 die every year, and probably from 3,000 to 5,000 are sick and disabled from the disease. Tuberculosis is a contagious disease; it is governed by the laws and conditions prevailing with other contagious diseases, and must be combated in a similar way. More persons die from it in this city than from all the other contagious diseases together, except pneumonia, if that is considered such. Is it not time that something more should be done by this city for its prevention?

"The knowledge now at command," says Drs. Biggs and Prudden in their report to the President of the New York Board of Health, "regarding the methods of extension of pulmonary tuberculosis, entirely justifies the belief that its ravages can as certainly be limited by proper sanitary control and appropriate treatment as can other infectious diseases, more acute, more dramatic, and more readily communicated, but at the same time far less prevalent, less fatal, and incomparably less important to the welfare of the community." "We firmly believe," they continue, "that with proper regulations tuberculosis may be restricted within the narrowest bounds, and eventually, perhaps, almost exterminated."

In conclusion, let me outline a plan for a systematic scheme of prevention in a city like this.

(1) Knowledge of all cases of tuberculosis and their habitat, and the power to control and supervise them; this knowledge to be obtained either by including consumption among the infectious and communicable diseases and requiring notification as with them — which I believe is the only thorough way — or by urging physicians through circulars from the Board of Health, frequently repeated, to report all cases coming within their observation, especially among the poor, or wherever there is doubt as to the proper disposal of the sputum.

(2) Instruction of the public as to the dangers of tuberculosis and their avoidance by circulars similar to those issued by the Pennsylvania Society for the Prevention of Tuberculosis. This is already done, I believe, to a greater or less extent.

(3) Compulsory disinfection or renovation of premises occupied by a consumptive, or in which a consumptive has died, before they can again be let or occupied.

(4) Hospital accommodations in especial buildings for poor consumptives and those of limited means, situated in or near the city, and receiving free all stages of the disease alike. Two such institutions with a capacity of 150 beds each, or three of 100 beds, would probably afford accommodation for 900 cases annually on the basis of an average residence of four months.

(5) One or more sanatoria proper in the country for the open-air treatment, not more than two or three hours distant from the city, where the incipient cases and those likely to be benefited by such treatment can be transferred from the city institutions. Rutland already accomplishes this to a limited extent.

(6) Free examination of sputum for tubercle bacilli, as is already done by the city and State.

(7) Regulations against spitting in public halls, conveyances and upon the sidewalks, such as already are in force in our street-car system, and in addition, the placing of spittoons in halls, waiting-rooms, stores, work-shops, out-patient waiting-rooms and possibly street-cars. In the writer's opinion, spitting properly conducted is a cleanly habit, and the deposit of sputum in appropriate receptacles is to be encouraged rather than in handkerchiefs or in the stomach. It seems a hardship to prohibit promiscuous spitting without making provision for a safe performance of this act, necessary to many persons.

(8) The establishment of especial out-patient clinics so that the consumptive cases can be segregated, and receive more detailed attention and instruction for themselves and friends as to how they may avoid communicating the disease.

(9) Control of the city milk supply, by requiring all dealers to furnish satisfactory evidence that the cows from which their milk is obtained have been found free from tuberculosis by the tuberculin test, which test is to be repeated at stated intervals.

(10) Inspection of animals slaughtered for food, and of all meat sent into the city. Possibly compulsory disinfection of old clothes in pawnshops, as advocated by Prof. Roche, of Dublin.[5]

Of all these, especial isolating hospitals are, in the writer's opinion, most urgent and most important.

[5] The Lancet, Feb. 11, 1899, p. 391.

THE USE OF ASTRINGENTS IN INTESTINAL CATARRH.

BY G. C. H. MEIER, M.D., NEW YORK,
Instructor in the New York Polyclinic.

WHEN the writer entered the practice of medicine, more than twenty years ago, the treatment of diarrheal affections comprised practically the use of opium, tannic acid, chalk, and bismuth subnitrate. In other words, the chief aim of treatment was to check the profuse diarrheal discharges as soon as possible.

With the development of the doctrine of the bacterial origin of many diseases, the treatment of intestinal disorders underwent a corresponding change, and thus arose what might be termed the antiseptic method of treatment. A large number of antiseptics have been proposed with a view of destroying the pathogenic organisms in the intestinal canal, and thus preventing fermentative processes. Among those which have chiefly claimed our attention are salicylic and carbolic acids, creosote, guaiacol-carbonate, resorcin and the various naphtol preparations. I have always been skeptical, however, as to whether the small doses of these drugs that can be administered with safety are really able to exert a sufficiently powerful antiseptic effect to arrest the growth of bacteria in the gastro-intestinal tract. That they effect some good I am firmly convinced, but I do not think that we should depend upon them completely to the exclusion of other remedial agents.

If we accept the modern theory, that many bowel troubles are due to toxic products generated by bacteria, it seems more logical to me to initiate the treatment of intestinal catarrhs with the use of some evacuant which will promote the elimination of toxins *per viam naturalem*. The drug most useful in my hands for this purpose is calomel, although castor oil may also be employed with good effects. The beneficial influence of calomel is shown by the change in the character of the stools. Castor oil also acts well, especially in the case of children, but is so objectionable to many persons that in most cases I prefer the use of calomel. Having freed the intestinal tract of all toxic irritating material, the diarrhea will sometimes cease under the administration of simple stomachics with bismuth. Often it is necessary to resort to further treatment before the profuse and exhausting discharges can be checked. Here is the proper field for intestinal astringents.

The list of intestinal astringents from which formerly we were compelled to make our choice was not a large one, comprising chiefly tannic acid and various preparations containing it, such as tinctures of kino and catechu and the mineral astringents, especially acetate of lead, sulphate of zinc, and sulphate of copper. The mineral astringents have the disadvantage of acting as irritants when given in doses sufficient to obtain their physiological effect, or of entering into inert combinations in the upper part of the intestinal canal. On the other hand, tannic acid and the various preparations containing it have the serious objection of irritating the mucous membrane of the stomach by acting upon the albuminous elements, and thus giving rise to more or less gastric disturbance. Much of the tannic acid administered probably undergoes absorption in the upper part of the bowels, or forms insoluble tannates which are devoid of any astringent action. In spite of these disadvantages, tannic acid has always been a favorite intestinal astringent. Lately chemical research has placed in our hands a number of new tannic-acid derivatives in which tannin is presented in a combination which passes unchanged through the stomach, and is gradually and slowly decomposed in the intestinal canal. The first of these preparations, introduced about four years ago to the medical profession, was tannigen or acetyl tannin. This preparation I have used quite considerably in my practice, but last year my attention was drawn to tannopine, a combination of tannin with urotropin, which I believe is superior to the former in many respects.

Tannopine contains 87 per cent. of tannic acid, and owing to its insolubility in fluids of acid or neutral reaction, it passes unchanged through the stomach, thus avoiding the irritating and even caustic effect of tannin upon the gastric mucosa. In the alkaline fluids of the intestine, tannopine is separated into its constituents, but this decomposition takes place so slowly and gradually that the astringent effect is not confined to the upper parts of the intestinal tract, as with most other remedies of this kind, but extends down to the lower part of the large intestine. Besides its astringent influence, tannopine also exerts an antiseptic action upon the intestinal contents. In my experience, it has never given rise to vomiting or irritation of the digestive tract, and as it is perfectly tasteless, it can be easily administered to children.

Dr. E. Schreiber[1] is the first to report his observations with tannopine, which were made in Professor Ebstein's clinic in Göttingen. His cases comprised acute and chronic enteritis, tuberculous enteritis, and typhoid fever, and in most instances the results were most encouraging. The diarrhea was promptly relieved without the least tendency to constipation. Schreiber warns us, however, not to discontinue the remedy too soon, in order to avoid recurrences. In typhoid fever attended with profuse diarrhea, tannopine rapidly reduced the number of passages, which also became firmer in consistence. In tuberculous enteritis it was found necessary to give the drug for a considerable time in order to effect any lasting improvement. In my article published in the *New York Medical Journal*, August 13, 1898, particular attention was directed to the value of tannopine in the chronic forms of diarrhea, especially common in adults and unattended with pain or nausea, the so-called chronic intestinal catarrhs. Excellent results were also obtained in cholera infantum, gastro-enteritis and dysentery. Since the publication of my article Dr. C. Fuchs[2] has reported his experience with tannopine in the medical clinic of Professor Drasche, of Vienna, and especially commends its action in cases of acute diarrhea, as well as in the diarrhea of intestinal tuberculosis. In chronic diarrhea its effect was found to be less certain, for while in some cases it arrested the diarrhea, in others it only diminished the number of evacuations.

Dr. G. Joachim[3] has particularly tested tannopine in cases of cholera infantum, cholera morbus and enteritis. In 19 cases of cholera infantum, in which profuse watery evacuations had been present for several days, tannopine acted very favorably. In 51 cases of gastro-intestinal catarrh tannopine was ad-

[1] Deutsche medicinische Wochenschrift, No. 49, 1897.
[2] Die Heilkunde, Hft. 11, 1898.
[3] Allgmeine medicinische Central-Zeitung, No. 65, 1898.

ministered in connection with minute doses (one-twelfth grain) of calomel, the latter being added for its disinfectant action. Good results were obtained in the majority of cases. In intestinal tuberculosis the results were much less favorable than those recorded by other authors. Joachim also points out that the remedy must be continued for some days after the cessation of the diarrhea in order to insure permanent cure.

Dr. J. Landau[4] has treated 79 cases of intestinal affections in children with tannopine, the majority being acute enteritis and gastro-enteritis, and most of the patients being below two years of age. He observed that under its administration in doses of four to eight grains four or five times a day, the diarrhea promptly subsided without the least disturbance of the digestive tract.

My later experiments with tannopine confirm the results of my former observations. I have found it to be even more efficient than tannigen in intestinal catarrhs, and especially adapted for children, as it is perfectly innocuous even in large doses. My experience embraces about 20 cases, and the results were particularly gratifying in the non-inflammatory forms of diarrhea, where the stools were frequent, watery, and passed without pain. Dietetic treatment should always be combined with the administration of tannopine. All food which is liable to fermentation and to increase the looseness of the bowels should be prohibited; a meat or milk diet should be strictly adhered to for some time, and sweets and pastry absolutely refrained from, as well as malt liquors and coffee.

Irrigation of the bowels with a warm normal salt solution will be found very grateful to the patient, particularly where there is some straining at stools, showing an involvement of the rectum. I have found it a good plan in the early stage of any diarrhea to administer a brisk purgative, such as castor oil or frequently repeated small doses of calomel, the latter acting at the same time as a disinfectant to the whole intestinal tract, checking fermentation and acting as a germicide to the bacteria present. Well-ventilated rooms and plenty of outdoor air also exert a favorable influence by their tonic power on the whole system and assist in overcoming the action of the toxins by increasing the vitality of the tissues.

The following cases taken from my record book illustrate well the conditions in which tannopine has proven most valuable in my hands, and will, I trust, be of interest to the reader:

Case I. Charley D., age five years, had been suffering for two days with vomiting and diarrhea, the stools being watery and containing shreds of mucus; no fever was present. He was put on calomel, one grain every hour, and the intestine flushed with sterilized salt water, using about two quarts injected as high up as possible. The vomiting ceased under this treatment, but the diarrhea continued, though with less frequency. Tannopine was now prescribed in eight-grain doses every three hours, and checked the discharge in two days. Treatment was continued for another day to assure a permanency of the cure, and the patient has since remained well.

Case II. Mrs. Th. M., fifty-nine years of age, suffers from chronic diarrhea, which makes its appearance whenever she is worried or angry. She is also affected with prolapsus uteri. Opium had a very disagreeable after-effect when given for the diarrhea, so she was just put on tannopine, ten grains three times a day, which succeeded in checking the discharge after a few doses, leaving no bad after-effects.

Case III. Walker B., age four months, bottle-fed, was taken with an acute attack of gastro-enteritis; temperature 104° (rectal); much pain. The baby was given a cool bath for ten minutes, which reduced the temperature to 101½°. Phenacetin, one grain, was prescribed every three hours, and a dose of castor oil administered. On the following day the child was much improved; the diarrhea, however, continued at intervals. Tannopine, three grains, was given every three hours for two days, and the child rapidly recovered.

Case IV. Will T., age twelve years, convalescing from an attack of pneumonia, complains of soreness in the abdomen and frequent watery discharges from the bowel. Tannopine, eight grains, was given three times a day, and rapidly effected a cure.

Case V. Henry D., age six years, suffers from prolapsus recti, and diarrheal passages. Injections of ice-water were prescribed after each passage, and tannopine, eight grains, every four hours in a little milk. Bismuth and chalk mixture had been of no avail previously, but tannopine rendered the stools firmer in consistence and kept the diarrhea perfectly in check.

Case VI. Grace D., age twelve years, complains of headache and diarrhea, which come on on alternate days. She has taken all kinds of diarrheal mixtures, with no permanent benefit. The child was ordered to take quinine, three grains, every three hours, and tannopine, five grains, after each stool. Both headache and diarrhea have disappeared. The quinine was continued for a week longer, and a few doses of tannopine were given every day. Result, no relapse.

Case VII. Harry B., age ten years, was seized suddenly with high fever, vomiting and diarrhea. The stools were slimy, but contained no blood; there was some tenesmus. A dose of castor oil was administered, and followed by five-grain doses of tannopine every three hours. The diarrhea was checked in twenty-four hours, and the passages became normal on the following day.

Case VIII. Sidney F., age nine months, was suddenly taken with convulsions and an elevation of temperature to 105° F. He was placed in a cool bath until the temperature was reduced to 102°. Then he began to vomit and purge; calomel, one-fourth grain, was given every half-hour until the discharges became spinach green. Vomiting ceased and the diarrhea became less frequent. Tannopine was now given in doses of three grains every two hours with the result that the stools were speedily changed to a normal consistence. At no time did tannopine produce any nausea or vomiting. It was generally given mixed with subnitrate of bismuth, either in some mucilaginous vehicle or in powders which were taken in milk.

In conclusion I would epitomize my experience as follows:

(1) That in all diarrheal affections of recent duration it is of the utmost importance to free the intestinal canal of all irritating material, preferably by the use of small doses of calomel.

(2) After this has been accomplished, it is usually

[4] Monatsschrift für praktische Medicin, December, 1898.

necessary to restore the tonicity of the relaxed intestinal mucous membrane and check the discharges by the use of astringents. In diarrheal affections of some days' duration, especially in children, it may be advisable to resort to the use of astringents at once in order to prevent exhaustion and collapse from the profuse and frequent evacuations.

(3) The best form in which to administer an intestinal astringent is one by which the astringent principle is slowly liberated in the intestinal canal so as to avoid any irritant effect upon the stomach, and also subject the lower intestinal tract to the influence of the remedy.

(4) Tannopine represents an efficient and reliable intestinal astringent, which, owing to its innocuousness, is well tolerated by the smallest children, and which, while an active astringent, is entirely free from irritating effects upon the intestinal canal.

Clinical Department.

SYPHILIS AND THE PARASYPHILITIC AFFECTIONS: TWO CASES.[1]

BY E. W. TAYLOR, M.D., BOSTON.

IT is evident that the last word has by no means been said regarding the etiological relationship of syphilis to the so-called parasyphilitic affections. That tabes and dementia paralytica occur frequently in persons with an antecedent syphilitic infection is unquestioned, but we need something more than coincidence to prove the point conclusively. A certain reactionary tendency is visible against the assumption of the close relationship between the two conditions, which has been generally accepted since Erb's statistics were published. For example, Guttmann,[2] in the study of 136 cases, found that 28.6 per cent. had had syphilis and 71.4 had not; six were doubtful. The occurrence of dementia paralytica as a sequence of syphilis is still less constant. It is not our purpose to discuss this difficult statistical question, but merely to draw attention to the fact that those cases in which there is a co-existence of symptoms of tertiary syphilis and the parasyphilitic affections are of particular clinical interest, and possibly are destined to throw some light on the matter. The following cases are also reported because of their somewhat unusual clinical course, and because of the difficulties attending their correct diagnosis.

CASE I. This patient, W. K., thirty-eight years old, claims to be a Moor, a statement which we have no reason to doubt. He was and is a man of good habits. His occupation formerly was that of a porter in a drawing-room car. In 1891 he was struck on the head in an accident, and from that time claims that he had certain mental peculiarities. He was married in 1890, and very soon thereafter contracted syphilis from his wife; he had a secondary eruption in 1891, was troubled in some way with his eyes, had much sore throat, some pain in the long bones of the legs, but no falling of the hair; a few months only after these symptoms, distinct delusions of grandeur developed, to which his mother also testified. He was under the impression that he had twenty-five students; that he was rich; that his mother was going to California in a private car. He also ordered his house carpeted at an expense of $500. He was at this time suspected by his employers of being mentally upset, and in 1893 was committed by Dr. Jelly to the Westboro Insane Hospital. He had had no definite and vigorous antisyphilitic treatment. He remained about six months at Westboro, without special treatment, and at the end of that time was taken home by his wife, who it is said gave him opiates for a period of eight months. Finally, in March, 1894, he was admitted to the Long Island Hospital, where I first saw him. He afterwards said that his memory had entirely failed at that time, that he did not know where he was, and that the first year of his residence at the hospital was practically a blank. During this period, which was before my connection with the hospital, he was unable to walk without assistance and declined absolutely to speak, but did not refuse food. It is probable that he had vague hallucinations of hearing, and at times he had attacks of violence. For several months before making a detailed examination I had observed the patient on my somewhat infrequent visits sitting passively in a chair, making no effort whatever to move, his face indicative of a deep depression, apparently regardless of his surroundings, and perfectly indifferent to his associates. He was being taken daily from his bed to a sun-room, where he spent most of his time, but remained for months perfectly speechless. Attempts to draw him out and elicit a word or two of recognition were absolutely ineffectual. He seemed depressed beyond the power to rouse, and it was for a time assumed that his refusal to walk was due rather to a mental inhibition than to a physical defect. This was, no doubt, in a small measure the case, but further examination revealed more adequate cause. It was as follows:

Motion.—There was slight tremor of the tongue; the cranial nerves showed no involvement. There was a much increased reflex at the wrist. The legs were emaciated without giving evidence of true muscular atrophy. Active and passive movements were both very deficient and conducive to spasm in hips and knees. Complete extension at the knees was not possible and he could not stand unsupported. The knee-jerks were much increased, but true ankle clonus was not obtainable. The gait was extremely spastic.

Sensation. — Muscle sense in the feet and toes retained; no objective disturbance of sensation. Slight urinary incontinence at night. Subjective complaint of paresthesia of legs.

Eyes. — Pupillary reactions normal; complains of a sensation of mist before the eyes, and states that at one time he had double vision.

Speech. — Hesitating in character when finally he began again to speak after being under treatment. The stock expression, "Third riding regiment of light artillery," was said with great difficulty, and he was utterly unable to repeat the alphabet spontaneously. The following is one of his attempts: *a, b, o, i, c, u, s, t, r, y, z, x, z*, with a tendency to go on indefinitely, and with no adequate consciousness that he was making mistakes.

As already indicated, the mental condition almost at once began to improve when active treatment of 100 to 200 grains of iodide of potash was instituted. He

[1] Read, in part, at a meeting of the Clinical Section of the Suffolk District Medical Society, March 15, 1899.

[2] Gutmann: Tabes Dorsalis und Syphilis. Zeitschr. f. klin. Med., xxxv, 1898, p. 242. Abstract in Journal of Nervous and Mental Disease, August, 1899.

seemed gradually to emerge from a state of absolute apathy, and mental blank such as one sees in infancy before the dawn of intelligence, into a state of receptivity. By degrees he relearned the alphabet, with the same effort that a child would have, and apparently with but small assistance from his previous knowledge. He studied laboriously to master the sequence of letters, in order to repeat them at the weekly visit, and finally after a long period of faithful effort was able to repeat them without mistake. With this reappearance of intelligence he gradually took more interest in his surroundings, occasionally smiled and could be drawn into more extended conversation. It was, however, not possible to learn anything definite of his mental state during his period of depression; there appeared, at least, to be no well-formed delusions to account for it. With the continuance of the iodide he improved rapidly. In the notes now at my disposal there is no mention of mercury, and my strong impression is that it was not given. After a time he began to walk without assistance, and his mental state rapidly cleared. He was somewhat troubled with urinary incontinence but not to a marked degree. His gait remained very spastic. This improvement took place in the course of about four months.

At the end of this time, the last note being July 31, 1894, he left the hospital and was not seen again until September 20, 1897. He had had no consistent treatment in the interval. Examination showed a persistence of the spastic gait, which had not improved; his bowels were regular in action and he was having no trouble with his urine. On October 4th he repeated the alphabet with some difficulty and omitted occasional letters; it was written also with several mistakes. The attempt to write from dictation "God save the Commonwealth of Massachusetts" resulted in an unintelligible scrawl, "God" being the only correctly written word. Repetition of difficult sentences was done badly, and reckoning was slow, but usually correct. He wrote his name correctly. His speech was not characteristic of general paralysis, nor was his appearance or manner. He was keenly conscious of his mistakes and apparently was embarrassed by them. Physical examination was as before. Deep reflexes remained much increased; of the superficial reflexes, the plantar was alone obtained. The pupils remained perfectly normal.

Treatment was again begun, and the iodide associated with mercury, first the biniodide and later inunction. In a few weeks the alphabet was again correctly written and great improvement noted in difficult sentences. As before, he took the greatest interest in his efforts in this direction. Repeated examinations showed no physical sign of significance other than those already noted. His frame of mind was one of entire satisfaction with his progress toward recovery, but his hopefulness could in no way be regarded as pathological.

On January 14, 1898, the note reads: "Says alphabet perfectly correctly; to-day repeats 'Third riding regiment of light artillery' quickly and correctly; does simple arithmetical examples well; is now taking charge of his mother's accounts." He has again a tendency to urinary incontinence. Has had no headache whatever.

Nearly a year later, December 27, 1898, he remained practically unchanged. I again quote from notes made at the time: "Does all the work at home, marketing, etc., and is able to get about better than before. At times legs feel stiff. Has taken no medicine for six months. Is satisfied with his condition; has had no trouble whatever in calculating (which his mother bears out); memory 'extra fine' now; shows no obvious speech defect. Has no discoverable delusions; no headaches. Has been going to night school for three months and is getting along well. Is now reading the second and third reader, which is not so far advanced as he was before his illness. It seems to him as if he were learning something entirely new, but it comes easier to him all the time."

Physical examination in March, 1899, gave the following results: Slight but definite ataxia of arms; legs somewhat weak; right pupil larger than left, with good light and accommodation reflexes; no diplopia; no headache; mental condition good; deep reflexes increased as before; right leg more spastic than left; abdominal, plantar, epigastric reflexes present; cremaster lacking; no facial tremor. Alphabet written with some mistakes, and unable to add 6+5. Multiplication well done. Repeats "Third riding regiment," etc., without faltering, and also without being asked what words to say, having remembered them from previous visits. The patient has not been seen for purposes of examination since.

Remarks. — This case offers many points of interest. In the first place have we to do with dementia paralytica with cord symptoms, or tertiary syphilis, or a combination of both? No doubt time is still required to answer this question with entire assurance. Pointing toward dementia paralytica we have the early symptoms of grandiose ideas, followed by a subsequent depressive stage, a by no means unusual occurrence. Cord degenerations are a frequent if not constant accompaniment of the cortical lesions, and should not in themselves exclude the diagnosis of general paralysis. The degree of spasticity and exaggeration of the deep reflexes, however, points rather toward a true syphilitic process. The marked tendency toward improvement under antisyphilitic treatment is rather against the idea of an uncomplicated dementia paralytica, though by no means absolutely conclusive. While fully aware of the danger of basing a diagnosis upon the results of treatment, this case seems one in which one might be allowed a little indulgence in spite of several recently expressed protests.[1] The effects of treatment may have been merely a coincidence, undertaken at times when improvement was about to take place spontaneously, or as Patrick points out, it is possible that antisyphilitic treatment may have some temporary effect upon dementia paralytica itself. My feeling, however, is that the evidence of treatment in this case is positive, and of considerable diagnostic value. There have been no epileptiform or paralytic seizures throughout the course of the disease.

When we turn to the second possibility of uncomplicated cerebro-spinal syphilis, we still have relatively little that is positive to go by. There have been no headaches, nor cranial nerve palsies beyond a doubtful diplopia, nor pupillary changes except a slight and recently developed inequality, which in any case is of small value in differential diagnosis.

[1] For a consideration of this and many other points of differential diagnosis between brain syphilis and general paralysis, see Patrick: New York Medical Journal, August 20, 24, September 10, 17, 1898; also Sachs: New York Medical Journal, May 27, 1899.

There has been absolutely no evidence of the usual multiple somatic signs of syphilis. The earliest obtainable symptoms were mental, and for those the patient was committed to an insane hospital. The character of the early delusions would point rather to dementia paralytica, though by no means pathognomonic. As an argument for syphilis we have the early manifestations of the cerebral lesions after the primary infection, a few months merely. The period of stupor and extreme depression following the early exaltation of ideas is rather more characteristic of syphilis than dementia paralytica. The cord symptoms point strongly to a syphilitic involvement of the type described by Erb. The improvement speaks for syphilis. As between the two conditions under consideration, therefore, the whole course of the disease points rather to cerebro-spinal syphilis than dementia paralytica.

The third possibility mentioned is altogether possible, that general paralysis has or will supervene in what is now a checked syphilitic process. It is to a careful study of these combined proliferative and degenerative lesions that we may look for a considerable amount of light in the future sifting of evidence regarding the etiological relationship of syphilis and the parasyphilitic affections.

CASE II. This case is of interest because of its obscurity for many years and its final definite outcome.

H., a married man of fifty-two, contracted syphilis in 1882. The infection was a source of great depression to him. He was treated for the disease by a skilled man, and since that time has repeatedly had antisyphilitic drugs, under the direction of as many as forty different physicians of note. He became notorious on account of his insistence on treatment, and came to be regarded as a person whose disease had so dominated his mind that argument was useless. He was, in other words, in the opinion of those who saw him, suffering from syphilophobia. In the course of his wanderings he had been to various psychiatrists, who recognized his depressed mental state, but attached no special significance to it. During the latter part of this period he became very much depressed, and continued so uninterruptedly for several years, in the meantime carrying on his work, that of a contractor, with success. His dominant thought seemed to be his infection, from which he apprehended various vague consequences.

I first saw him January 25, 1898, shortly after his return from Hot Springs, Arkansas, where he had again been undergoing vigorous treatment, which ended in marked mercurialization. Since his return he has had slight false ideas resulting from salivation. Examination showed that he had never had headache, diplopia, or cerebral symptoms of any sort. He complained of disturbance of sensation in the hands and feet for about two years, and, at times, of a feeling of constriction about the waist, but has had no urinary or rectal disturbance. Sexual intercourse was less satisfactory than heretofore. He has had pains in the legs for some time, which were apparently lancinating in character. He was able to make all movements of arms and legs without ataxia; there was no Romberg; gross strength was unimpaired. The knee-jerks were absent, as was also the cremaster reflex; other peripheral reflexes were normal and active. There were many subjective disturbances of sensation in the hands and feet and particularly on the outer side of the left thigh. Tests for touch and pain showed nothing abnormal, excepting at times a slight confusion of the head and point of a pin. There was a slight disturbance of muscle sense in the toes. The pupils were perfectly normal in size and contour, and gave an excellent reaction both to light and accommodation. There was not a suggestion of any speech defect.

The most striking thing about the patient was his excessive talkativeness and introspection. His one object appeared to be to exhaust his medical adviser with a detailed description of his symptoms, always with syphilis in the background. As is usual in such cases, his acquaintance with drugs was pitiful in its completeness, and his general knowledge of just how to take care of himself was as remarkable as his devotion to doctors. It seemed, however, a common enough type, and certainly suggested nothing deeper than an extreme hypochondriasis, just as it had impressed others before. The diagnosis reached was early tabes dorsalis and syphilophobia.

From this time until the latter part of February, I was besieged with well written and highly detailed letters of his condition from day to day, and of the exact amounts of the various drugs which he had prescribed for himself, as he afterwards reproachfully told me. The symptoms were insignificant and the letters quite in accord with the earlier opinion. Not a suspicion had entered my mind of a degenerative brain affection, or even of cerebral syphilis.

Finally, on February 24th, he failed to keep an appointment, and I went to the house. The whole situation was changed. His persistent mood of hypochondriasis, which had lasted for many years, had entirely passed. His son told me that his father had been acting strangely for some time, and distinctly different from his usual habit. He had grown jealous and suspicious of his wife; had spoken in a bantering way to a washwoman; had been alluding to himself in an unusually satisfied way, and had within a few days bought a valuable piece of land on a main street for the purpose of building. He was, when seen, in a very exhilarated frame of mind regarding the above business venture, which he thought an excellent one. He said he had bought a piece of land for $12,000, for which he proposed to pay cash; for this purpose he had sold well-paying bonds. He said he was worth $70,000; that he had made an excellent, long spiritual prayer, that he had a remarkable flow of speech. He had been writing a great many letters regarding building and had prepared plans of a house on slips of paper with many figures and estimates; one of them was headed: "Father's Birthday, Heaven," with the date. One letter of twelve pages was sent to a contractor, effusive in character and ending with "Amen." He claimed that he was a spiritualist, and telepathist and believed in the presence of departed spirits. He was previously not at all religious.

These examples suffice to show what an absolute change had come over the patient's thoughts. The diagnosis, unsuspected to this time, was clear, and subsequent events confirmed it. The pupils, however, were normal, and there was still no speech defect. Dementia rapidly supervened; his letters showed characteristic omissions and mistakes; he gained in weight; a variety of delusions developed; he drank excessively before being finally committed to a hospital. When last seen, about a year after first coming under observation, he presented a perfectly typical

figure of general paralysis. He had had apoplectiform attacks, which had not before occurred, and was rapidly failing.

This case requires but little comment. Its interest to those who saw it is much greater than can possibly be conveyed to the reader. The simulation of a simple hypochondriasis was complete for a long period of years. This hypochondriasis, in the light of the outcome, is rather to be regarded as an extraordinarily long depressive stage of dementia paralytica. To make that diagnosis, however, with sufficient assurance to check the reckless expenditure of money appears to have been impossible. The cord symptoms, distinctly of a tabetic type, are also of considerable interest, and were likely to mislead, in the absence of typical mental symptoms, as, in fact, they did. The case did not have that generally progressive character, which Patrick [4] speaks of as characteristic, nor did anything like typical mental symptoms (if there be typical symptoms in general paralysis) dominate the clinical picture. We are of the impression that up to the time when grandiose ideas first presented themselves a dogmatic diagnosis could not have been made, in spite of the fact that the disease was already of long standing.

The two cases taken together are instructive. In one the symptoms of cerebro-spinal syphilis were at first obscured by signs pointing to general paralysis, and in the other the symptom-complex of general paralysis emerged only after years of atypical symptoms, which were unrelieved by faithful antisyphilitic treatment. The lessons of these and similar cases are manifold. They deserve and demand the most painstaking study, for just this relationship and confusion between the syphilitic and parasyphilitic affections affords one of the most difficult and important diagnostic problems with which we have to deal.

Medical Progress.

REPORT ON PROGRESS IN PATHOLOGY.

BY JAMES H. WRIGHT, M.D., BOSTON,
Director of the Laboratory of the Massachusetts General Hospital.

PARASITES AND CARCINOMA.

N. G. Plimmer [1] describes and figures peculiar bodies observed by him in the tumor cells in a large number of cases of carcinoma. These are similar in appearances to some of the bodies which have been described by various other observers in recent years and to which various names have been given. Like many others, Plimmer regards these as parasites. He states that in a single case he has succeeded in obtaining cultures of the organism by the use of a special culture medium made from carcinomatous tissue. This organism seem to be allied to the blastomycetes. It grows best under anaërobic conditions. Inoculated into animals it produces multiple tumor growths of an endotheliomatous character.

THE PATHOGENIC ACTION OF YEASTS.

Alex. G. R. Foulerton [2] studied the effect of the inoculation of animals with various species of blastomycetes. He found that with some species tumor formations at the point of inoculation were produced and in some instances metastatic tumors in the internal organs as well. His attention, however, was chiefly devoted to the pathogenic action of a yeast which he isolated from two cases of pharyngitis. This he proposes to call *saccharomyces tumefaciens albus*. It was actively pathogenic for tame mice and for rabbits, less so for guinea-pigs. In rabbits tumors were produced at the seat of inoculation with secondary tumors in various organs, in some cases. In the mice no tumor formations were observed. Histologically the tumor growths were composed of mononuclear round cells. Rarely large cells containing the organism were seen.

TUBERCLE BACILLI IN THE MILK OF TUBERCULOUS COWS.

The bacteriological examination of milk for tubercle bacilli has given varying results on the hands of different bacteriologists. Thus, among others, Obermüller found the bacilli in 61 per cent. of samples of milk sold in Berlin, while Petri only found them in 14 per cent.

The question of the frequency of the occurrence of tubercle bacilli in milk and of the value of the tuberculin reaction as indicating the probable presence of tubercle bacilli in the milk, has been investigated by Lydia Rabinowitsch and Walter Kempner [3] in the Institute for Infectious Diseases and in the Pathological Institute of the Veterinary High School of Berlin. Of 25 samples of milk from various sources 7, or 28 per cent. contained tubercle bacilli.

As to the frequency of the occurrence of the bacilli in the milk of cows known or suspected to be tuberculous, there are wide differences in the results of various investigators. Thus Nocard found them in the milk in only 5.5 per cent. of the cows, H. C. Ernest, of Boston, in 28.6 per cent., and Hirschberger in 55 per cent.

There seems to be a general agreement that the milk of cows with well-marked tuberculosis is very apt to contain tubercle bacilli and that such milk should not be used without sterilization. On the other hand, there is much difference of opinion with regard to the infectiousness of the milk of cows with only slight tubercular lesions and without apparent disease of the udder, or of cows which react to tuberculin without clinical signs of tuberculosis. Rabinowitsch and Kempner examined the milk of 15 cows which had reacted to tuberculin. In the milk of 10 of them, or in 67 per cent., they found tubercle bacilli.

Of the 10 positive cases there was tuberculosis of the udder in only two. In three there were no definite clinical signs of tuberculosis and in one only very early pulmonary lesions. The remainder were more or less extensively affected by the disease.

The authors conclude from their study that the milk of apparently healthy cows, which react to tuberculin, or of cows in the early stage of tuberculosis without involvement of the udder, may contain tubercle bacilli. Although the number of observations was small they think that they are justified in the opinion that the milk of cows which react to tuberculin should be regarded the same as milk from frankly tubercu-

lous cows, and that the surest way to keep a milk supply free from tubercle bacilli is by the use of the tuberculin test.

EXPERIMENTAL HEMOGLOBINURIA.

Dr. Anton A. Christomanos,[4] working in the Physiological Institute at Athens, Greece, has availed himself of the fact that subcutaneous injections of glycerin cause hemoglobinuria to study the blood and organs of rabbits so treated. He finds that the glycerin produces a thickening of the blood by abstraction of water and also produces a hemoglobinemia. The blood corpuscles which become useless from loss of hemoglobin are deposited in the spleen and bone marrow, where they are taken up by large cells. The number of red corpuscles in the blood is at first apparently increased, and this is due to the abstraction of the water by the glycerin, but soon, within four to five hours after the injection of the glycerin, a diminution in the number of red corpuscles becomes evident. The size of the corpuscles is also diminished by the glycerin. The free hemoglobin in the blood plasma does not enter the renal tubules from the glomeruli but is deposited in the epithelial cells of the renal tubules from the intertubular capillaries and from these cells it makes its way into the lumina of the renal tubules, where it may be accumulated to such an extent as to completely fill them. Most of the tubules of the kidney may be thus occluded.

EXPERIMENTAL CASEOUS PNEUMONIA.

J. Auclair[5] makes a contribution to the subject of the etiology of the caseous pneumonia of pulmonary tuberculosis. This lesion is considered by some to be due to the action of other bacteria than the tubercle bacillus, or, in other words, to be due to a secondary infection of the lung by pyogenic bacteria. On the other hand some believe that the condition is due to the effects of soluble poisons derived from the tubercle bacilli in the ordinary tubercular lesions elsewhere in the lung.

In previous publications[6] Auclair has shown that a poison may be extracted from tubercle bacilli, by means of ether or chloroform, or xylene or benzine, which is capable of producing suppuration and caseous degeneration of animal tissues.

In the present paper he has studied the effect of intratracheal injections of the ethereal extract in animals. He finds that such injections produce all stages and appearances of caseous pneumonia and he considers that he has clearly demonstrated that caseous pneumonia is due to the action of the poisons produced by the tubercle bacilli and not to secondary infections of the lung with other bacteria.

THE ETIOLOGY OF BERI-BERI.

Yamagiva[7] contributes an exhaustive report of his observations on this disease in Japan. He concludes that the disease is due to the daily use of an inferior kind of boiled rice. This food material produces a form of chronic intoxication which is characterized by a contraction of the arterioles throughout the body. From this there result hypertrophy and dilatation of the heart, anemia of the skin and mucous membranes and of the nerves and muscles, together with regressive changes in these organs and tissues owing to the anemia.

THE BACTERIAL FLORA OF THE LUNGS.

L. Beco[8] has made an extensive study of healthy lungs of man and animals with reference to the question of the presence or absence of bacteria in them.

As regards the healthy lung of both domestic and laboratory animals his conclusions are in part as follows: The bacteria usually present in the upper air passages do not invade the lung after death. When the lung is sterile at the moment of death it behaves as a closed organ as far as concerns the invasion of putrefactive bacteria from the intestine. If, at death, the lung is infected, the bacteria in it may rapidly multiply and, in the case of putrefactive bacteria, a rapid putrefaction may result with extension to neighboring organs. In the case of strictly pathogenic bacteria, however, the invasion of neighboring organs is slow and only occurs exceptionally.

For his study of the subject on the lung of man he selected 20 cases in which the lung appeared normal and in which bronchial lesions were absent. Among these were six cases in which death had occurred suddenly during complete or relatively good health.

From these cases the following results were obtained: The inferior respiratory tracts in the healthy man may be sterile, but frequently in lungs free from any gross lesions pathogenic bacteria may be present, usually in small number. These bacteria are those which are the usual infectious agents in acute pulmonary infections, namely, the pneumococcus, streptococcus and the staphylococcus (rarely). It is probable that during the last hours of life, or during the agony, and proportionately to the length of the same, there occurs an invasion of the lung by the bacteria of the upper air passages. Under the usual conditions, however, this invasion does not occur after death. Further, if various species of bacteria have invaded the lung, there may be observed after death a diminution in the number of these species.

The tubercle bacillus could not be demonstrated in the healthy lung although it was sought for in 11 of the cases.

THE IMPLANTATION OF EMBRYONIC CELLS IN THE ANIMAL BODY.

A. Birsch-Hirschfeld and Garten[9] report the results of the injection of freshly disintegrated tissues of young embryos into the liver of adult animals. In the goat, rabbit, chicken, salamander and frog, tumor-like new growths of cartilaginous tissue were obtained in the liver and lungs. In the chicken, after some weeks, adenoid structures, epithelial-like cells and pigmented cells, were found in the liver. The injected cells clearly seemed to have differentiated themselves in the animal body. The experiments were most successful when accompanied by a periodic stimulation of the liver tissue. The growth of the embryonic tissue was only transitory. After weeks and months the tumor-like new growths became encapsulated and regressive changes set in. Finally resorption of the tissue took place.

THE HISTOGENESIS OF ORGANIZING PNEUMONIA.

Prof. Ribbert,[10] of Zurich, has studied this interesting condition with the aid of serial sections and a modification of Mallory's staining method. He confirms the view that the branching masses of connective tissue, which invade the air cells of the lung and which are so characteristic of the process, have their origin in the bronchioles and smallest bronchi. In early cases an organic connection of this tissue with the alveolar walls cannot be demonstrated, but such connection can always be seen with the walls of the smaller branches of the bronchial tree. The process consists in an outgrowth of connective-tissue cells and embryonic blood-vessels into the exudate which fills these canals and the air cells.

BACTERIOLYTIC ENZYMES AND ACQUIRED IMMUNITY.

R. Emmerich and O. Loew[11] have made an interesting contribution to the subject of immunity to infectious diseases. They report the results of a long series of experiments, their summary of which is essentially as follows: The cessation of growth which is observed in most cultures of bacteria before all the nutrient substances are used up is due to the development of an enzyme-like substance which is formed by the bacteria themselves. This substance is capable in turn of destroying and dissolving the bacteria. Some of these enzymes can not only destroy and dissolve the same species of bacteria which produced them, but they can also destroy other species of bacteria.

The curative effects of the so-called products of metabolism of bacteria or of unfiltered cultures of bacteria is due to the action of these bacterial enzymes in the culture fluids.

The artificial immunity produced by the products of bacterial metabolism or by cultures of pathogenic bacteria is due to the fact that the bacteriolytic enzyme combines slowly with an albuminous substance in the blood. The resulting compound has the same bacteria-destroying powers as the original enzyme itself. This combination, which takes place in the animal body only, slowly and with great waste of enzyme, may be produced rapidly *in vitro* by chemical action. We are now, therefore, in a position, at least in some of the infectious diseases, to produce artificially an antitoxic serum without the aid of the animal organism.

The so-called "agglutination" or "clump reaction" is nothing but the first stage of the bacteria-destroying power of a bacteriolytic enzyme combined with the albumin of the blood.

The serum of immune animals is much more bactericidal in its effects in the absence of air than in the presence of air. This is a fact that has been completely overlooked. By great concentration of such serum marked bactericidal effects may be produced even in the presence of air.

Some bacterial enzymes when introduced into the animal body act not only destructively upon the bacteria which may be present, but also upon the bacterial poisons or toxins. Thus, for example, the enzyme of the *bacillus pyocyaneus* can completely neutralize the fatal effects of the toxin or poison produced by the *diphtheria bacillus*.

Judging from the experiments on animals, the enzyme of the *bacillus pyocyaneus* should be suitable for the successful treatment of anthrax, plague, diphtheria, etc., in man. By means of an antitoxic serum produced artificially *in vitro* with the enzyme of the *bacillus pyocyaneus* an immunity against anthrax of a high grade may be produced in animals.

The bactericidal effect of normal blood is probably also due to enzyme-like substances in it. The fact that high concentration of normal blood gives it the property of agglutination for certain bacteria is a point in favor of this idea.

SITUS VISCERUM INVERSUS.

Arnold Koller[12] describes a new case of this rare anomaly and adds an account of the theories which have been advanced concerning its origin. He also describes several cases of malformation and some experiments on freshly fertilized fish eggs, which have a bearing upon Förster's view that in all double monsters one fetus shows the *situs inversus*.

He thinks that, according to our present knowledge and in the light of his own observation, the *situs inversus* can be most simply explained upon the assumption of a symmetrical double fetus formation, in which the fetus possessing the normal arrangement of its viscera has disappeared. He finds that Förster's view, that *situs inversus* is always found in one fetus in the case of double monsters, is not true. It does occur, but not in all cases. Double monsters may be produced experimentally by various means applied directly after the fertilization of the egg. Their formation is due to the abnormal character of the sexual elements or to the effect of various influences acting immediately after the fertilization.

SCARLET FEVER.

R. M. Pearce[13] reports the results of a thorough pathological and bacteriological study of 23 autopsies on scarlet fever performed in the Pathological Laboratory of the Boston City Hospital.

No specific infectious agent was found which could be regarded as the cause of the disease. Anatomically, the only constant lesion found was a hyperplasia of the lymphadenoid tissue everywhere, especially in the lymphatic glands. The lesion was particularly marked in the lymphadenoid structures of the intestine.

In only a few cases was a pseudo-membrane present on the tonsils. In this streptococci were found but never diphtheria bacilli.

The most frequent complications were otitis media and bronchopneumonia.

In 11 of the cases there was a general infection with the pyogenic cocci, the streptococcus being present in nine of the cases. The infections with these organisms are regarded as secondary, for in all but two of the cases there was some inflammatory condition which could be regarded as an infection atrium.

The most prominent histological changes observed were as follows: In the skin, congestion of the blood-vessels, dilatation of the lymphatics and infiltration with polymorphonuclear leucocytes. In the tongue this condition was much more marked, and here there were also degeneration and necrosis of the epithelium. Similar changes were also present in the mucous mem-

brane of the pharynx and in neighboring structures. In a few cases small streptococcus abscesses were observed in the lymphoid tissue of these parts.

The most striking changes in the lymphatic glands and in the spleen were the proliferation of the endothelial cells and the presence of plasma cells. The proliferated endothelial cells were often phagocytic. The behavior of these cells here is similar to their behavior in typhoid fever, as recently described by Mallory. These same conditions were not only present in the larger lymphatic glands, but also in the smaller aggregations of lymphadenoid tissue along the respiratory and gastro-intestinal tracts.

In the mucous membrane of the gastro-intestinal tract there were found degenerative changes in the epithelium and an increased number of plasma cells and eosinophilic leucocytes besides the changes in the lymphadenoid tissue above mentioned.

Fatty degeneration of the muscles of the heart was observed in five of these cases and fragmentation of the muscle fibres in three cases.

In four cases focal necroses were found on the liver. These seem to originate in the same way as the hepatic lesions recently described by Mallory in typhoid fever. They apparently are due to circulatory disturbances in the capillaries caused by the occlusion of capillaries with endothelial cells which are derived either from the endothelium of the liver, or from the endothelium of other organs, which reach the liver by embolism. In one of these cases a necrosis of the cells of the central parts of the liver lobule was observed. These are regarded by Pearce as due to the effect of a toxin in the circulating blood acting on that portion of the lobule where the circulation is slowest.

In the cases studied by Pearce no examples of glomerulonephritis were met with, although one of the forms of this renal condition is commonly thought to be a not infrequent complication of scarlet fever. The author thinks that this may be due to the fact that his cases were for the most part too recent for these renal lesions to develop. In eight cases, however, more or less well-marked acute interstitial changes were observed in the kidneys, characterized by the presence of plasma cells in the interstitial tissue. These cases have been more fully described by Professor Councilman[14] in a recent paper on acute interstitial nephritis.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting Wednesday, March 15, 1899, DR. H. F. VICKERY in the chair.

DR. W. H. SMITH showed a specimen of

ACUTE ENDOCARDITIS OF THE TRICUSPID VALVE.

DR. E. W. TAYLOR read a paper entitled

SYPHILIS OR DEMENTIA PARALYTICA; A CASE FOR DIAGNOSIS.[1]

[1] See page 286 of the Journal.

[14] Transactions of the Association of American Physicians, 1898.

DR. VICKERY: Were any vasomotor symptoms such as flushings or sudden pallor recorded?

DR. TAYLOR: It would be difficult to tell about flushing in this case as the patient's color was very dark. In general, I did not discover any vasomotor symptoms.

DR. F. H. WILLIAMS: I think we all feel indebted to Dr. Taylor for presenting an interesting and rare case so clearly. Nothing can be said in addition to what he has stated; it certainly is a very unusual case, and one very well worthy of record.

DR. E. O. OTIS presented a paper entitled

THE STRUGGLE AGAINST TUBERCULOSIS.[2]

DR. KNIGHT: I think that Dr. Otis has certainly covered the ground very thoroughly on this subject. It seems to me that there has been a reluctance on the part of city, State and national governments to take hold of this question on account of its size; it seemed too big a subject to tackle, the disease seemed too widespread. In talking with several officials they have expressed that opinion. They felt that something ought to be done, but the subject was so big they didn't like to take hold of it. There is no doubt about the diminution in mortality of tubercular disease, particularly in Great Britain and in this country. This has been attributed in England largely to the increase in the number of hospitals and consequent treatment and isolation. In this country it cannot be attributed to this, but I think is attributed more to our knowledge of the disease and improved hygiene, improved modes of life, outdoor life and outdoor treatment. It seems curious that the United States, generally quick in adopting new methods of treatment, should be so far behind in this question of the establishment of hospitals for consumptives, but we are very far behind most of the European countries, and I am glad to see that Dr. Otis is making an effort in the right direction. When I appeared several times before the Finance Committee at the State House with regard to the Rutland Hospital I was surprised to find how well disposed every man of that committee was toward the project. They said: "This does not seem to be enough. You want more than one hospital for this purpose. You will want certainly three in Massachusetts." And I said: "Yes, we shall. We ought to have one in the city, one in the central and one in the western part of the State." And they seemed quite willing, if they were in power when the time came, to make appropriations. It seems to me the community would tolerate even the reporting of cases. That has been one great bugbear, that there would be a resentment in regard to reporting cases, that the people would not stand it, but, as far as I have seen, the people seem to be willing to do anything which is going to diminish the mortality of this disease. For instance, how quickly everybody obeyed the order in regard to spitting in the cars. I was astonished to see how quickly the cars, from being very filthy, became clean. People obeyed the admonition of the Board of Health. So I think, even if an order was issued that cases should be reported, though at first people might resent it, yet I think they would soon take it as they do the reporting of diphtheria or any other infectious disease, provided that the official visit, if one was necessary, was made in the proper way. It seems to me that now is the time to act in this matter, that

[2] See page 280 of the Journal.

people have been educated up to that point in which they will approve of appropriations, and the legislatures will be willing to make appropriations for isolating hospitals as well as for those for incipient cases. When the appropriation was made for Rutland I think that the members of the committee supposed that they were establishing a home for consumptives, but the trustees when they came to consider the working of the hospital thought it would be better to make the first institution an institution for the cure of early cases. I am not sure they were not right. Certainly it is more interesting for the staff who have to attend them. But we want and want badly the other class of institutions — the institutions for the isolation of the advanced cases, because it is from the advanced cases that the disease is mostly spread in the community, and I think that if a determined effort is now made for one large institution of that kind near the city, where patients can be visited by their friends, the great majority of whom live in the city, it can be obtained. The establishment of others for incipient cases will follow naturally.

Dr. V. Y. Bowditch: I can add very little to Dr. Otis's paper; only emphasize certain points he brings up. In the first place, having the privilege of being one of the attending physicians at the new State Hospital for Consumptives at Rutland, Mass., I think it would be perhaps of interest if I spoke of one or two facts which I have noted since the opening of the hospital in October. I confess when it was first opened I had some doubt as to how far it would be successful in getting the kind of case we wished; not the dirty poor, but the respectable poor, and I felt it was questionable whether they would be content to go together in the open wards. There are a few private rooms in case of severe illness, but as a rule the patients are in open wards. I have been perfectly astonished to see the philosophy with which all these patients came under the treatment and the cheerfulness and even pleasure with which they seemed to undertake whatever was mapped out for them in the way of treatment. Undoubtedly there is a moral influence from the mere fact that they are in an institution or sanitarium where a certain amount of military discipline exists, which I cannot — and I think that is the experience of most physicians — accomplish in private families. You cannot get the open-air treatment in a private house, except in occasional cases, as you can in an institution of that sort. These patients sleep in an atmosphere that at home would be almost impossible. The windows are open and at first in the coldest winter weather the patients would naturally complain of its being cold, but I have been astonished to see how quickly they become accustomed to it and like it. We have already had one or two cases of patients going home previous to the time advised but who have begged to be taken back, because, as they expressed it, "they could not breathe at home."
